ABSTRACT

A new determination of the sound horizon scale in angular coordinates is presented. It makes use of \(~ 0.6 \times 10^9\) luminous red galaxies, selected from the Sloan Digital Sky Survey imaging data, with photometric redshifts. The analysis covers a redshift interval that goes from \(z = 0.5\) to 0.6. We find evidence of the baryon acoustic oscillation (BAO) signal at the \(\sim 2.3\sigma\) confidence level, with a value of \(\theta_{\text{BAO}}(z = 0.55) = (3.90 \pm 0.38)\), including systematic errors. To our understanding, this is the first direct measurement of the angular BAO scale in the galaxy distribution and it is in agreement with previous BAO measurements. We also show how radial determinations of the BAO scale can break the degeneracy in the measurement of cosmological parameters when they are combined with BAO angular measurements. The result is also in good agreement with the 7-year Wilkinson Microwave Anisotropy Probe (WMAP7) best-fitting cosmology. We obtain a value of \(w_0 = -1.03 \pm 0.16\) for the equation of state parameter of the dark energy, or \(\Omega_M = 0.26 \pm 0.04\) for the matter density, when the other parameters are fixed. We have also tested the sensitivity of current BAO measurements to a time-varying dark energy equation of state, finding \(w_a = 0.06 \pm 0.22\) if we fix all the other parameters to the WMAP7 best-fitting cosmology.

Key words: methods: data analysis – cosmological parameters – dark energy – large-scale structure of Universe.

1 INTRODUCTION

The baryon acoustic oscillation (BAO) signal imprinted in the galaxy distribution was first convincingly detected in 2005 (Eisenstein et al. 2005), using the Sloan Digital Sky Survey (SDSS)¹ data (York et al. 2000). Since then, several more detections at different redshift intervals have been done (Percival et al. 2007; Gaztañaga, Cabré & Hui 2009; Sánchez et al. 2009; Kazin et al. 2010a; Percival et al. 2010; Reid et al. 2010). These papers have all used spectroscopic data in order to calculate galaxy redshifts and positions and have inferred cosmological parameters through an averaged three-dimensional evaluation of the BAO scale.

Furthermore, the purely radial BAO signal was first obtained in Gaztañaga et al. (2009), where they measure the redshift intervals that correspond to the sound horizon scale at different redshifts. There are ongoing or proposed projects like Baryon Oscillation Spectroscopic Survey (BOSS) (Schlegel et al. 2007) or BigBOSS (Schlegel et al. 2009) that will use massive measurements of galaxy spectra to obtain new measurements of the BAO scale, more precise and deeper than current determinations.

The feasibility of measuring the BAO signal using photometric redshifts (photoz) was first demonstrated in Padmanabhan et al. (2007) (see also Blake et al. 2007; Thomas, Abdalla & Lahav 2011). Large multiband imaging surveys are a powerful way to explore the clustering properties of galaxies. Their advantage is the possibility of mapping wider areas in deeper volumes, compared with spectroscopic surveys. However, the precision of the photoz is worse than its spectroscopic counterpart. There are projects like the Dark Energy Survey (DES) (The Dark Energy Survey Collaboration 2005), the Panoramic Survey Telescope & Rapid Response System (PanSTARRS) (Kaiser, Tonry & Luppino 2000) or the Large Synoptic Survey Telescope (LSST) (Tyson et al. 2003) that aim to obtain the most precise cosmological constraints using imaging alone, compensating the lack of precision in redshift, with a larger volume and higher galaxy density, and also with the possibility of studying different galaxy populations.

In this paper, a new determination of the BAO angular scale is presented. The measurement has been done upon a photometric sample of luminous red galaxies (LRGs), obtained from the SDSS seventh data release (DR7), published by Abazajian et al. (2009). We study the BAO signal at a redshift interval that goes from \(z = 0.5\) to 0.6, using the photometric sample described in the companion paper (Crocce et al. 2011b). This measurement is the first direct detection...
of the purely angular BAO signal, and it is complementary to the purely radial BAO and to the three-dimensional averaged BAO signal, contributing to break degeneracies in the determination of cosmological parameters.

We use a model-independent method to measure the angular BAO scale with precision (Sánchez et al. 2011). The method is based on a parametrization of the angular correlation function as a sum of a power law, a constant and a Gaussian. There are a total of six parameters and the BAO position and its significance are given by the location and signal-to-noise ratio in amplitude of the Gaussian. It is robust against systematic errors, it uses only observable quantities and it is independent of any assumption about other parameters or the shape of the correlation function. Furthermore, we have evaluated the systematic errors associated with the measurement.

The paper is organized as follows. First, we briefly explain the LRG selection criteria, that is common with the companion paper (Crocco et al. 2011b). Then, the measurement of the angular BAO scale in the two-point angular correlation function is discussed. Next, we combine this result with previous measurements of the averaged and radial BAO scales to obtain new cosmological constraints, and finally, we comment on the conclusions.

2 SELECTION OF THE GALAXY SAMPLE

We perform a colour-based selection of LRGs in the SDSS DR7 imaging sample, based on that published by Cabrén et al. (2006). The selection is described in more detail in the companion paper (Crocco et al. 2011b). First, we select the region in the colour–colour space that is populated by LRGs (Eisenstein et al. 2001), requiring 

\[(r - i) > (g - r)/4 + 0.36 \quad \text{and} \quad (g - r) > -0.72(r - i) + 1.7.\]

Then, we minimize the star contamination, imposing an additional set of cuts: 

- \[17 < r_{\text{Peto}} < 21, \quad 0 < \sigma_{\text{Peto}} < 0.5, \quad 0 < (r - i) < 2, \quad 0 < (g - r) < 3\]
- \[22 < \mu_{50} < 24.5 \text{mag arcsec}^{-2}.\]

In these cuts, \(g, r\) and \(i\) are the model magnitudes corrected by extinction, \(\sigma_{\text{Peto}}\) is the error on the Petrosian magnitude \(r_{\text{Peto}}\) and \(\mu_{50}\) is the mean surface brightness within the Petrosian half-light radius in the \(r\) band. Finally, only galactic latitudes \(b > 25^\circ\) are considered. A total of \(\sim 1.5 \times 10^6\) objects are selected, with a star contamination of 4 ± 1 per cent, determined using the spectroscopic SDSS sample.

We use the angular mask depicted in Fig. 1 as a Mollweide projection in equatorial coordinates, which amounts to a total area of 7136 deg\(^2\). Only the largest contiguous area of the survey is considered in this analysis. There is also a vertical band in the mask that it is excluded due to the photoz catalogue we have used, described in the next section. For further details, see Crocco et al. (2011b).

3 CORRELATION FUNCTIONS

The photometric redshift determination developed in Oyaizu et al. (2008) is used in this analysis. It is combined with the value added catalogue of Cunha et al. (2009), where the photometric redshift probability distribution function (PDF) for every object is given, following the method of Lima et al. (2008). We determine the redshift for each object as the maximum of its PDF, and the full PDF distribution is used to estimate the true distribution of objects with redshift. Objects with PDF distributions that do not satisfy good-quality requirements are rejected (see Crocco et al. 2011b for a detailed description of the photometric redshift quality requirements). The highest redshift region, \(0.5 < z < 0.6\), is chosen for this analysis. It contains \(0.61 \times 10^6\) objects.

We chose this bin width for two reasons. First, a much narrower bin does not enhance the sensitivity, due to the dilution effect caused by the photoz. Secondly, a much wider bin will decrease the amplitude of the correlation function, making it more difficult to detect the BAO signal.

Fig. 2 shows the measured angular correlation function (dots) in this redshift bin. It has been computed using the Landy and Szalay estimator (Landy & Szalay 1993).

The error and covariances in the angular correlation function have been evaluated using three independent methods. First, we have generated 50 artificial realizations of the observed \(\omega(\theta)\). The error is computed as the dispersion of the generated realizations, taking into account the fraction of the sky that the survey covers. Secondly, we...
have used the standard jackknife procedure, dividing the area into 80 regions. Thirdly, we have used the theoretical description, following the result in Crocce, Cabre & Gaztañaga (2011a). The three determinations agree within 25 per cent in the square root of the diagonal elements of the covariance matrix. To see a more detailed discussion of the error calculation, see Crocce et al. (2011b).

4 RESULTS

We use the method described in Sánchez et al. (2011) to measure the BAO scale, using the observed correlation function of the previous section. The method is based on the description of $\omega(\theta)$ as the sum of a power law to describe the continuum and a Gaussian peak to describe the BAO feature:

$$\omega(\theta) = A + B\theta^\gamma + C e^{-(\theta-\theta_{\text{FIT}})^2/2\sigma^2}.$$  

(1)

This expression is fitted to the data with free parameters $A$, $B$, $C$, $\gamma$, $\theta_{\text{FIT}}$ and $\sigma$. The true BAO scale is recovered from the fitted parameter $\theta_{\text{FIT}}$ after correcting for the projection effect due to the width of the redshift bin where the analysis is performed:

$$\theta_{\text{BAO}} = \alpha(z, \Delta z) \theta_{\text{FIT}}.$$  

(2)

The factor $\alpha$ is taken from the analysis presented in Sánchez et al. (2011) and depends on the redshift, $z$, and the redshift bin width, $\Delta z$.

The fit is presented in Fig. 2 (solid line), compared to a single power law (dotted line). This fit includes the full covariance matrix, obtained with the jackknife method, as seen in the companion paper. In Crocce et al. (2011b) we calculate both the jackknife and the analytical covariances, finding that both are compatible with each other and that the results do not depend on the chosen covariance matrix (Crocce et al. 2011b).

The BAO peak is detected with a statistical significance of 2.3 standard deviations. The statistical significance is computed using two methods. First, we use the fitted parameter $C$ from equation (1), and we quote the significance as its difference from zero. Secondly, we compare the result with a theoretical model that includes the BAO wiggles and with a model that does not include them [this comparison is fully described in Crocce et al. (2011b)]. Both determinations agree in the significance of the detection.

4.1 Systematic errors

The main systematic errors affecting this measurement have been described in Sánchez et al. (2011), and we add them to our error budget here, except for the photometric redshift, which is recalibrated. The reason for this recalibration is that the photometric redshift in SDSS is not perfectly Gaussian (Fig. 3), as it was supposed in Sánchez et al. (2011).

We have recalibrated the photoz error by calculating the dispersion in the BAO scale if we compute $\omega(\theta)$ with different photoz codes, all contained in the SDSS DR7 catalogue. We redo the full analysis using the photometric redshift given by the photodz1 and also by using the full PDF as the redshift, and not only the maximum probability. In the latter case, all galaxies have a probability to lay within the selected redshift bin, for example, in the redshift bin $0.5 \leq z \leq 0.6$. The only difference in the numerical algorithm is that, instead of calculating distances between pairs of galaxies, now we calculate distances between probabilities of galaxies and weight the distance depending on the probability of pairs in the given bin.

We found that the amplitude of the correlation function does change, being smoother if we use the full PDF, but the measured scale $\theta_{\text{BAO}}$ is stable within 2 per cent for all cases, including the photodz1 estimation. Therefore, we add a contribution of 2 per cent, coming from the different photoz code used, to the 5 per cent found in Sánchez et al. (2011), which only accounts for the smearing of the photz in an ideal Gaussian case. The total systematic error due to photometric redshift is then $\Delta \theta_{\text{BAO}}(\text{photz}) = 7$ per cent.

Moreover, there are some additional effects that need to be taken into account on top of those of Sánchez et al. (2011). These are the effects related to the selection of the sample (selection cuts, mask and contamination).

To evaluate the systematic error associated with the selection criteria, we vary the selection cuts of Section 2 and recompute $\omega(\theta)$. Then, we compare the new measured $\theta_{\text{BAO}}$ with the nominal value. We have tested variations in $\mu_{\text{SD}}$, $(r-i)$ and $(g-r)$ within 10 per cent of their nominal limits in Section 2. The maximum variation found is $\Delta \theta_{\text{BAO}}(\text{selection}) = 2.5$ per cent, when we vary the $\mu_{\text{SD}}$ limits. In all cases, variations in $\theta_{\text{BAO}}$ are always below the statistical uncertainty, which in our case is $\sim$5 per cent. $\Delta \theta_{\text{BAO}}(\text{selection}) = 2.5$ per cent is assigned as the systematic error due to the sample selection. This is actually likely to be conservative and most likely larger than the true 1$\sigma$ value, but it is almost negligible compared to the 7 per cent uncertainty of the photoz and the 5 per cent statistical uncertainty.

We have also varied the mask in order to assess further uncertainties in our result. First, we relax the cut in $b > 25^{\circ}$ and allow areas with $b < 25^{\circ}$. The effect of this cut in the galaxy number density can be seen in fig. 3 of the companion paper Crocce et al. (2011b). There is a gradient in the number density of galaxies at low galactic latitudes, implying that there is a population of objects, belonging to our Galaxy, that is contaminating the sample. The effect in $\theta_{\text{BAO}}$ is similar to the effect that we obtain when we vary the galaxy selection cuts. Both produce smooth distortions in the clustering signal.

We also compute $\omega(\theta)$ for different quality values of extinction, seen at the bottom panel of fig. 4 in the companion paper Crocce et al. (2011b). We eliminate areas with extinction higher than 0.15, 0.2 and without limits. Variations in $\theta_{\text{BAO}}$ are almost negligible, as we are dominated by the statistical error. For the mask, the strongest difference occurs if we allow areas with $b > 20^{\circ}$. The variation is of 2 per cent, associated with the mask systematic error as $\Delta \theta_{\text{BAO}}(\text{mask}) = 2$ per cent.

Figure 3. The true redshift distribution of selected galaxies. It has been obtained summing all the galaxies PDFs within the bin. The vertical lines are the limits of the photometric redshift bin under study.
We recall that both error estimates are likely to be overestimated, although both are almost negligible in comparison with the statistical error of 5 per cent and the photoz systematic error of 7 per cent, and, therefore, considering the level of precision in the data, we believe it is reasonable to follow this prescription.

The influence of star contamination has also been checked. We have fitted the correlation function including the star contamination as a constant factor, multiplied by the star correlation function (see Crocce et al. 2011b). The influence is found to be negligible, since the correlation function of stars varies very slowly with the angular scale. Variations in \( \theta_{BAO} \) are \( \Delta \theta_{BAO}(\text{stars}) < 0.1 \) per cent. Moreover, we have included different levels of star contamination in the theoretical correlation functions presented in Sánchez et al. (2011), always as a constant factor multiplied by the star correlation function. We have applied our method to all of them and found that the \( \theta_{BAO} \) obtained with our parametrization is insensitive to the presence of stars, at least for contaminations up to 10 per cent.

The full accounting of systematic errors is presented in Table 1. The total systematic error budget is \( \Delta \theta_{BAO}(\text{sys}) = 8.0 \) per cent.

About the significance of the detection, we found that the effect of these systematics in the significance can produce maximum changes of the order of 10 per cent, up to a significance of 2.6σ, if we cut in \( b \simeq 20^\circ \) and using the maximum probability as the redshift and the nominal colour cuts. We do not find any clear correlation with selection cuts or with the photoz code we used. This is due to the fact that we are yet limited by statistical uncertainties and the smearing of the photoz.

### 4.2 Comparison with previous measurements

The fitted angular scale, associated with the BAO scale, is \( \theta_{\text{FIT}}(z = 0.55) = 3.48 \pm 0.19 \) obtained upon a redshift bin of width \( \Delta z_{\text{photo}} = 0.1 \). Following Sánchez et al. (2011), this value must be corrected to obtain the true BAO angular scale, \( \theta_{BAO} = \sigma(z, \Delta z) \theta_{\text{FIT}} \). For this redshift and bin width, the correction is \( \sigma(z = 0.55, \Delta z_{\text{true}} = \sqrt{2\pi\Delta z_{\text{photo}}}) = 1.12 \). The final result for the BAO scale, including statistical and systematic errors, is \( \theta_{BAO}(z = 0.55) = 3.90 \pm 0.38 \).

The evolution of the angular BAO scale with redshift is presented in Fig. 4. The measurement presented in this analysis is the solid dot, including the statistical and the systematic errors. The other measurements are inferred from the given reference, by translating the three-dimensional averaged distance parameter \( D_V \) into an angular scale, with the fiducial cosmology used in each reference.

All the measurements are in agreement with the 7-year Wilkinson Microwave Anisotropy Probe (WMAP7) cosmology to better than 1σ, represented by the solid line. The band includes the uncertainty in the determination of the Hubble constant \( H_0 \).

We have tested the sensitivity of current BAO measurements to a dark energy with an equation of state parameter that varies with time, as \( w(a) = w_0 + \omega w_s (1 - a) \), where \( a \) is the scalefactor of the Universe. In Fig. 5 (left) we show the allowed regions for parameters \( w_0 \) and \( w_s \), when we fit the evolution of the BAO scale using the data in Fig. 4, plus the radial BAO scales at \( z = 0.24 \) and 0.43 from Gaztañaga et al. (2009), whose values are \( r_s(z = 0.24) = 110.3 \pm 2.9 \pm 1.8 \text{Mpc}\, h^{-1} \) and \( r_s(z = 0.43) = 108.9 \pm 3.9 \pm 2.1 \text{Mpc}\, h^{-1} \). We fix all the other cosmological parameters to their values in the WMAP7 w cold dark matter (wCDM) cosmology (Komatsu et al. 2011), and we use the most recent Hubble constant determination (Riess et al. 2011). We have chosen the values of Percival et al. (2007) at \( z = 0.20 \), Percival et al. (2010) at \( z = 0.275 \), Sánchez et al. (2009) at \( z = 0.35 \) and the measurement presented in this paper at \( z = 0.55 \), since the other measurements at the same or similar redshifts are strongly correlated. Data are compatible at the 1σ level with a dark energy that behaves as a cosmological constant (\( w_0 = -1, w_s = 0 \), included as the solid dot in Fig. 5).

We have also studied the sensitivity of current BAO measurements in the plane \( w, \Omega_m \), under the same conditions as above: we use the same data points and also include the radial BAOs. The other parameters remain fixed plus \( w_s \), which is fixed to zero. The result is presented in Fig. 5 (right). The dash–dotted line shows the expected value for the cosmological constant, compatible with the data.

If we fit to a single parameter, it gives \( w = -1.03 \pm 0.16 \). The data are compatible with a cosmological constant with a precision of ~20 per cent in \( w \). If we do the same study for \( \Omega_M \), we find a value of \( \Omega_M = 0.26 \pm 0.04 \). Both measurements include systematic

---

**Table 1.** Estimation of systematic errors in the determination of \( \theta_{BAO} \). Those above the horizontal line are taken from Sánchez et al. (2011), except the error coming from the photometric redshift, which has been recalibrated for this work. The others are the main new contributions that arise from a real photometric redshift survey.

| Systematic error          | \( \Delta \theta_{BAO} \) |
|---------------------------|---------------------------|
| Parameterization          | 1 per cent                |
| Photometric redshift error| 7 per cent                |
| Redshift space distortions| 1 per cent                |
| Theory                    | 1 per cent                |
| Projection effect         | 1 per cent                |
| Selection of the sample   | 2.5 per cent              |
| Survey mask               | 2 per cent                |

---

**Figure 4.** The angular BAO scale as a function of redshift. The measurement presented in this paper is the solid dot. Its error includes both the statistical and systematic contributions. The other measurements are inferred from the given reference by translating the three-dimensional averaged distance parameter \( D_V \) into an angular scale, with the fiducial cosmology used in each reference. All of them are compatible with the WMAP7 cosmology (solid line). The band includes the uncertainty in the Hubble constant \( H_0 \).

Some of the measurements at \( z = 0.35 \) have been slightly displaced in redshift for clarity.
Implications from the baryon acoustic scale

Figure 5. Constraints in the equation of state of the dark energy using the data in Fig. 4 and the radial BAO measurements from Gaztañaga et al. (2009). Left: constraints in the plane $w_0, w_a$, where $w(a) = w_0 + w_a(1 - a)$, and $a$ the scalefactor of the Universe. Data are compatible with a dark energy that behaves as a cosmological constant to better than 1σ (solid dot). Right: constraints in the plane $w, \Omega_m$. The dash–dotted line corresponds to the cosmological constant and is compatible with the data.

Figure 6. Left: the contribution of our determination $\theta_{\text{BAO}}(z = 0.55)$, to the dark energy equation of state constraints. The bold contour is the full combination, while the light contour is obtained when excluding our measurement at $z = 0.55$. The contribution of this new measurement is not negligible, improving by 5 per cent the figure of merit. Right: contribution to the cosmological constraints from the angular (light vertical contour) and radial (light diagonal contour) BAO scale measurements. Both determinations are complementary, and the combination (bold contour) breaks the degeneracy, making the constraints more precise.

errors, and have been obtained fixing all the other parameters to the same values as above, except $H_0$, which has been varied within its uncertainty. We have now included the influence of $H_0$ because it is larger in this case. The error budget in the parameter becomes 40 per cent larger, including the $H_0$ uncertainty. The influence in the previous two-dimensional constraints is smaller.

The influence of our measurement in the cosmological constraints is shown in Fig. 6 (left), where we compare the constraints at 68 per cent confidence level (CL) for all the data (bold) with the constraints obtained when the point of this study $(z = 0.55)$ is excluded (light). The contribution of the new point is not negligible, since its inclusion makes the constraints more precise. In particular, the figure of merit, defined as the inverse of the area within contours, improves by 5 per cent. Moreover, we have studied how the angular and the radial BAO scale measurements contribute to the cosmological constraints. This is depicted in Fig. 6 (right), where the light vertical contour corresponds to the angular BAO scales and the light diagonal contour corresponds to the radial BAO scales. The bold contours are the full combination at 68 per cent CL, also presented in Fig. 5 (right). Both determinations are complementary and the combination clearly breaks degeneracies between cosmological parameters, enhancing the sensitivity.

Some comments about the detection of the radial BAO are in order, since there are some claims saying that there is no convincing...
evidence of the detection (Kazin et al. 2010b). For them, detection means a preference for a model with BAO as compared to a model without BAO. Nevertheless, we also consider the appreciation given in Cabré & Gaztañaga (2011), who argue that it is not justified to use any of the current BAO measurements (radial or not) to do a clear model selection. Instead, Cabré & Gaztañaga (2011) show that BAO measurements can be used for parameter fitting within CDM models, which is what we present here.

5 CONCLUSIONS

We have measured the BAO signal in the distribution of galaxies at the redshift interval 0.5 < z < 0.6, using an LRG sample selected from the SDSS DR7 photometric catalogue. The BAO signal is detected with a statistical significance of 2.3 standard deviations, as expected from the characteristics of the sample (Crocce et al. 2011b). The result is in agreement with the WMAP7 cosmology; we find θ_{BAO}(z = 0.55) = (3.90 ± 0.38) for the angular BAO scale, including systematic errors. This is the first direct measurement of the BAO signal in angular space and complements previous three-dimensional averaged and radial BAO measurements, making a significant contribution to break degeneracies between cosmological parameters. Combined with previous BAO measurements, this translates into ω = −1.03 ± 0.16 for the equation of state parameter of the dark energy, and Ω_M = 0.26 ± 0.04 for the matter density.

Our relative error determination in the angular BAO scale is 9 per cent. This is larger than the 6.5 per cent uncertainty found by Padmanabhan et al. (2007), the only previous photometric determination of the BAO scale. This difference is not totally surprising, since our method to recover the BAO position only uses the information around the BAO peak, while Padmanabhan et al. (2007) include all scales with k > 0.3. The impact and analysis of systematic effects are also quite different. For example, the above error in Padmanabhan et al. does not include the photometric redshift uncertainties, while this effect dominates our systematic error budget (see Table 1).

We have also studied the sensitivity of all BAO measurements obtained up to date, to a time-varying dark energy equation of state, finding Ω_{DE} = 0.06 ± 0.22 when we fix all the other parameters to the WMAP7 cosmology. Therefore, the data are well described by a dark energy that behaves as a cosmological constant.

This study is a confirmation of the feasibility to obtain precise cosmological constrains using photometric redshift surveys. This allows wider and deeper galaxy samples, with the caveat of a less precise redshift. However, the smaller precision in the redshift determination is compensated with the higher statistics, allowing precise measurements of cosmological parameters.
