We report the enhanced thermoelectric properties of Ce-doped AgSbTe$_2$ (AgSb$_{1-x}$Ce$_x$Te$_2$) compounds. As the Ce contents increased, the proportion of heterophase Ag$_2$Te in the AgSbTe$_2$ gradually decreased, along with the size of the crystals. The electrical resistivity and Seebeck coefficient were dramatically affected by Ce doping and the lattice thermal conductivity was reduced. The presence of nanostructured Ag$_2$Te heterophases resulted in a greatly enhanced dimensionless figure of merit, ZT of 1.5 at 673 K. These findings highlight the importance of the heterophase and doping control, which determines both electrical and thermal properties.

Thermoelectric (TE) power generators can be used to recycle waste heat from automobiles and incinerators. Although these devices are reliable and compact, the low energy conversion efficiency is a main drawback for TE power generation$^{1,2}$. The efficiency of TE power generators is limited by the temperature environment and TE figure of merit (ZT) of the materials used, as follows: $ZT = S^2T/\rho \kappa$, where $S$ is the Seebeck coefficient, $\rho$ is the electrical resistivity, $\kappa$ is the thermal conductivity, and $T$ is temperature in Kelvin$^{3,4}$. Several efforts have been made to improve ZT.

Recently, the compound AgSbTe$_2$ has been investigated as a potentially important component in high-performance bulk nanostructured TE materials, such as the LAST-m, ((PbTe)$_m$(AgSbTe$_2$)$_{100-m}$) and TAGS-x ((GeTe)$_x$(AgSbTe$_2$)$_{100-x}$)$^{5-9}$. There is much interest in nanocomposite materials comprising heterophases which are embedded in the matrix$^{10-13}$.

AgSbTe$_2$ is also important by itself due to its good TE properties combined with relatively low thermal conductivity (0.6–0.7 W/mK)$^{14-16}$. Wang et al. reported that AgSbTe$_2$ has a high $ZT = 1.59$ at 673 K due to its extremely low thermal conductivity$^{16}$. Also, some papers have reported good TE properties in the non-stoichiometric compositions formed by controlling the secondary phase, such as nanoscaled Ag$_2$Te and Sb$_2$Te$_3$.$^{17,18}$ Others have tried to not only reduce the lattice thermal conductivity but also adjust the carrier concentrations using dopants such as Na, Se, and Mn in AgSbTe$_2$.$^{19-21}$, by suppressing the formation of impurity phases, they enhanced the TE properties. It is clear from the research mentioned that large-scale precipitates have a deleterious impact on TE properties, whereas the formation of nanoscale dispersion enhances these properties. Interfaces within a TE material have been shown to reduce the thermal conductivity without degrading the electrical conductivity$^{22,23}$.

In this work, we investigated the influence of Ce doping on the microstructure and TE properties of Ag$_{1-x}$Ce$_x$Te$_2$ as we varied the Ce concentration (x = 0–0.004). We found that the proportion of Ag$_2$Te was significantly influenced by the Ce dopant, leading to improvements in the ZT value. To our knowledge, this is first observation of ZT enhancement arising from controlling the Ag$_2$Te phase by doping. Du et al. reported on the effect of Ce on excess Te in AgSbTe$_2.01$ compounds$^{24}$. However, they did not sufficiently explain their results in terms of their impact on TE properties, particularly in relation to the morphology, or the effects of doping the compound with Ce. In comparison to their results, our results show considerably different transport properties. In practice, the carrier concentration and mobility were considerably different in our work. This difference may be attributable to a different fabrication process and the composition of the samples, which may result in

different microstructures. A spark plasma sintering method was used in ref. 24., while a hot-pressing method was employed here to solidify samples, as well as the sintering temperature and pressure were also different, resulting in development of different morphologies. However, they did not report on the microstructure of their samples.

In a related development, Marin et al.25. reported that the physical properties of single-crystalline samples of this material vary as a result of micro-fluctuations in the chemical composition. We demonstrate experimentally that doping AgSbTe2 systems with Ce is an effective approach for improving TE performance by reducing thermal conductivity and adjusting carrier concentrations; specifically, Ce doping enables control over the proportion of Ag2Te heterophases in the matrix AgSbTe2.

Results and Discussion

The samples were obtained from sintering powders with hot-pressing method, in which the powders were obtained from melting elemental materials in quartz tubes with the nominal composition of AgSb1−xCexTe2 (0.001 ≤ x ≤ 0.004). Figure 1 shows the X-ray diffraction (XRD) pattern in Ce-doped AgSbTe2 compounds, obtained from the powder of the sintered samples. The phase of the AgSbTe2 and the small amount of Ag2Te were detected in all samples. The crystal structures of AgSbTe2 were identified as they caused disordered NaCl structures (space group, Fm3m), in which the Ag and Sb were located at the Na site. A small amount of Ag2Te secondary phases were identified along with the main cubic phase. It should be noted that the exact crystal structure of AgSbTe2 is currently a subject of debate, so we do not know, for example, whether it is crystallized in R3m, P4/mmm and etc.26, 27. We attempted to refine the AgSbTe2 structure based on the model of the disordered NaCl structure (Fm3m) and different models of ordered structures (R3m, P4/mmm and, Fd3m) using the Rietveld refinement method. Our Rietveld refinement analysis revealed that it was not easy to distinguish the crystal structure of AgSbTe2, is currently a subject of debate, so we do not know, for example, whether it is crystallized in R3m, P4/mmm and etc.26, 27. We attempted to refine the AgSbTe2 structure based on the model of the disordered NaCl structure (Fm3m) and different models of ordered structures (R3m, P4/mmm and, Fd3m) using the Rietveld refinement method. Our Rietveld refinement analysis revealed that it was not easy to distinguish the crystal structure based on the statistical results from the refinement: the Rwp and χ² values are 7.85/2.08 in Fm3m, 7.91/2.10 in R3m, 7.71/2.45 in P4/mmm, and 7.76/2.05 in Fd3m, respectively. Thus, we consider the space group of AgSbTe2 to maintain consistency with many other studies.

The cell parameters obtained from the refinement gradually decreased as the proportion of Ce increased. The small amount of Ce led to small changes: 0.6079 nm at x = 0; 0.6078 nm at x = 0.001; 0.6072 nm at x = 0.002; 0.6068 nm at x = 0.003; and 0.6066 nm at x = 0.004. This reduction was not attributed to the substitution of Ce for Sb or Ag, because the atomic or ionic radius of Ce is larger than that of Sb and Ag. Notably, it was found that the lattice parameters decreased with the amount of Ag2Te18. We speculate that the reduction in the lattice parameters is due to the reduction in the amount of Ag2Te. This speculation is supported by other observations detailed in the rest of this article.

Quantitative analysis of Ag2Te was carried out using the Rietveld refinement method. The results are shown in Table 1. The Ag2Te ratio decreased from 9.5% to 2.0%; the peaks also broadened with Ce doping. The peak broadening was analyzed using the Williamson–Hall equation:

Table 1. 

| Sample     | Detected Ce contents (ICP) | Rexp | Rwp | χ² | Ag2Te wt% | Cation sites occupancy |
|------------|----------------------------|------|-----|----|----------|------------------------|
| AgSbTe2    | Non                        | 3.78 | 7.85| 2.08| 9.5%     | 0.754 1.074 0.702      |
| x = 0.001  | Non                        | 7.07 | 8.23| 1.16| 6.2%     | 0.772 1.078 0.716      |
| x = 0.002  | x = 0.0037                 | 4.81 | 8.00| 1.66| 6.0%     | 0.784 1.066 0.735      |
| x = 0.003  | x = 0.0056                 | 4.72 | 9.79| 2.07| 4.2%     | 0.97 1.136 0.854     |
| x = 0.004  | x = 0.0111                 | 3.89 | 9.66| 2.48| 2.0%     | 0.974 1.136 0.857     |

Figure 1. X-ray diffraction (XRD) patterns of Ce-doped AgSb1−xCexTe2 samples; the phase of the AgSbTe2 and the small amount of Ag2Te were detected in all samples; the right panel is the patterns focused on the region between 27.5 and 43 degrees.
where $\beta$ is the integral breadth of the diffraction peak, $\lambda$ is the X-ray wavelength, $d$ is the average grain size, $\theta$ is the Bragg diffraction angle, and $\varepsilon$ is the microscopic strain\(^2\). The crystal size decreased as the amount of Ce increased: 71.8 nm at $x = 0$; 55.9 nm at $x = 0.001$; 47.3 nm at $x = 0.002$; 35.4 nm at $x = 0.003$; and 34.5 nm at $x = 0.004$.

To determine the microstructure of the compound, SEM images were obtained (Fig. 2). The continuously segregated precipitates of Ag\(_2\)Te in the melted ingot at the grain boundaries are clearly shown in Fig. 2(a), in which the SEM and elemental mapping images of the ingots obtained after the melting–quenching cycle are shown. It is clear that the Ag\(_2\)Te phase formed after the solidification of AgSbTe\(_2\). The segregated precipitates were crushed during pulverization of the ingot and remained as isolated precipitates in the sintered samples, as shown in Fig. 2(b). The light and dark regions were Ag\(_2\)Te precipitates and AgSbTe\(_2\) matrix, respectively. Nano-sized precipitates were not observed in the images. Additionally, the amount of Ag\(_2\)Te precipitate decreased as the amount of Ce increased, as shown in Fig. 2(c–e). The size of each precipitate was also reduced, in agreement with our XRD analysis.

Figure 2. (a) SEM images and the elemental distribution of AgSbTe\(_2\) ingots quenched after melting; the region of grain boundaries was identified as Ag\(_2\)Te precipitates, (b–e) SEM images of the hot-pressed samples; the light and dark regions are Ag\(_2\)Te precipitates and AgSbTe\(_2\) matrix, respectively; the precipitates crushed from melted ingots remained as isolated precipitates in the sintered samples, (b) AgSbTe\(_2\), (c) $x = 0.002$, (d) $x = 0.003$, and (e) $x = 0.004$ samples in AgSb\(_{1-x}\)Ce\(_x\)Te\(_2\).
The reduced amount of Ag$_2$Te was also confirmed by differential scanning calorimetry (DSC) measurements. The endothermic peaks at 423 K can be observed in the DSC curves shown in Fig. 3. The peak at 423 K corresponds to the phase transition peaks from $\alpha$-Ag$_2$Te to $\beta$-Ag$_2$Te. The intensity decreased with Ce doping, which is related with the decreased Ag$_2$Te ratio. The sample mass is 50 mg.

The broad bump in the temperature dependence of the Seebeck coefficient as $\rho = 1/\sigma \mu e$, where $\mu$ and $e$ are the mobility and carrier charge, respectively. Table 2 shows the carrier concentration and the mobility of Ce-doped AgSbTe$_2$ compounds at room temperature. The positive Seebeck coefficient and Hall coefficient indicate that the major carriers are holes. The carrier concentration increased with the amount of Ce added, whereas the mobility of the Ce-doped compound was lower than that of the undoped compound. Thus, the reduced electrical resistivity of the Ce-doped compound, except for $x = 0.001$, was mainly caused by changes in the carrier concentration. The reduction in the Seebeck coefficient as Ce is added can also be attributed to the carrier concentration, because $S$ depends on $S \sim \rho^{-2/3}$ in highly degenerate semiconductors. The reduced mobility is thought to be due to the finer crystallite size in the Ce-doped AgSbTe$_2$. Ag$_2$Te acts as a minor carrier in the p-type AgSbTe$_2$ matrix, so by decreasing the proportion of Ag$_2$Te, the carrier concentration can increase.

The temperature dependence of the power factor ($S^2/\rho$) is shown in the inset of Fig. 4(b). The maximum value of 1.55 mW/mK$^2$ at 673 K was achieved in the $x = 0.002$ sample. The enlarged power factor at elevated temperatures for the Ce-doped compound was mainly due to the reduced electrical resistivity.

In Fig. 4(c), the solid shapes represent the temperature dependence of the total thermal conductivity ($\kappa$), while open/empty shapes are the lattice thermal conductivity ($\kappa_l$) of the Ce-doped AgSbTe$_2$ compounds. The lattice thermal conductivity can be evaluated by subtracting the electronic contribution ($\kappa_e$) from the total thermal conductivity ($\kappa$), $\kappa_{ph} = \kappa - \kappa_e$. $\kappa_e$ can be estimated using the Wiedemann–Franz law, $\kappa_e = LT/\rho$, in which $L$ is the
Lorenz number. The value of $L$ is largely dependent on the position of the Fermi level and the scattering mechanism. It can be calculated using:

$$L = \left\{ \frac{k}{e} \right\} \frac{(1 + \lambda)(3 + \lambda)F_1(E_F(\eta)F_{2+\lambda}(\eta)) - (2 + \lambda)^2F_{1+\lambda}(\eta)^2}{(1 + \lambda)^2F_1(\eta)^2}$$

(2)

where $\lambda$ is the scattering factor ($\lambda = 0$ for acoustic phonon scattering and $\lambda = 2$ for ionized impurity scattering) and $F_1(\eta) = \int^{\infty}_{E_F(\eta)} f(-\xi) d\xi$, where $f(-\xi)$ is the Fermi distribution, $\xi$ is the reduced energy of the carriers, and $\eta$ is the reduced Fermi energy.\35,\38 Assuming acoustic phonon scattering and determining the value of $\eta$ from the measured Seebeck coefficient according to Eq. (3), we were able to calculate the value of $L$, which is shown in the inset of Fig. 4(c):

$$S = \left\{ \frac{k}{e} \right\} \frac{(2 + \lambda)F_{1+\lambda}}{(1 + \lambda)F_1} - \eta$$

(3)

All Ce-doped samples had lower total thermal conductivity and lower lattice thermal conductivity than the ternary compound. The lattice thermal conductivity for the $x=0.002$ sample was $0.44$ W/m·K at room temperature and $0.43$ W/m·K at 673 K, which is $30\%$ lower than the lattice thermal conductivity of the ternary compound ($\kappa_{\text{ph}} = 0.66$ and $0.6$ W/m·K at room temperature and 673 K, respectively). The total thermal conductivity

Table 2. Carrier concentration and the mobility of Ce-doped AgSb$_{1-x}$Ce$_x$Te$_2$ samples.
was in the range of 0.6–0.8 W/m·K, similar to that observed in a previous report. In the inset of Fig. 4(c), the measured specific heat capacity ($C_p$) of the AgSbTe$_2$ samples was used to calculate the total thermal conductivity. The values are 0.217 J/g·K at room temperature and 0.251 J/g·K at 673 K; these values are significantly higher than the literature value ($C_p = 0.205$ J/g·K) of AgSbTe$_2$.

The reduction in $\kappa$ as Ce was added was mainly due to the reduction in $\kappa_{ph}$. To investigate the origin of the reduced $\kappa_{ph}$, we observed the nanoscale microstructures of the samples using TEM. The images obtained are shown in Fig. 5. The nanostructures with a size of about 10 nm were identified as Ag$_2$Te, which is expected from the $d$-spacing (0.32 nm) of (112). This finding contrasts with the image of AgSbTe$_2$ matrix. Only the Ag$_2$Te monoclinic phase has the same $d$-spacing size in the possible phases like Ag$_2$Te, Sb$_2$Te$_3$, and AgSbTe$_2$ in this system. Also, if the nanodots are the Sb$_2$Te$_3$ phase, it will be shown brightly compared to AgSbTe$_2$ matrix in the bright field image of TEM. The difference in the size of the nanostructures was insignificant after annealing at 673 K for 24 h, as shown in Fig. 5(c) and (d). It is well known that the nanostructures are major phonon scattering centers and

![Figure 5](image1.png)

**Figure 5.** (a) Transmission electron microscopy (TEM) images of the $x = 0.002$ sample in AgSb$_{1-x}$Ce$_x$Te$_2$, (b) magnified images of Ag$_2$Te nanostructures, (c) TEM images after annealing at 673 K for 24 h, and (d) histogram of nanodots with respect to size.

![Figure 6](image2.png)

**Figure 6.** Comparison of the ZT values: Data 1–9 are from ref. 13, 40, 41, 42, 20, 17, 19, 16 and 43, respectively.
lead to a reduction in the level of lattice thermal conductivity. For example, 80% of phonons in PbTe have a mean free path below 100 nm and are effectively scattered by nanostructures. Thus, we think that the reduced $\kappa_{ph}$ of the Ce-doped samples was mainly caused by the existence of nanostructures, as nanostructured Ag$_2$Te was not observed in the ternary compound. Furthermore, the finer crystallite sizes in the Ce-doped compound also contribute marginally to the reduction in $\kappa_{ph}$.

Figure 4(d) shows the effect of temperature on ZT. The value of $ZT = 0.92$ at 673 K for the undoped sample is lower than the value reported in the literature ($ZT \approx 1.2$). The measured value of $\kappa$ was larger than previously reported, although the values of $S$ and $\rho$ were similar. We speculate that the difference is due to the use of a much higher value of $C_p$, which is not well defined in previous studies. The maximum value of $\kappa$ was 1.5 at 673 K. This was observed using the $\kappa = 0.002$ sample. This $ZT$ value is ~39% higher than that of the undoped sample. The thermal stability of the TE performance was observed after annealing at 673 K for 24 h. The $ZT$ value was almost maintained at 1.49 at 673 K. The reductions in $\kappa_{ph}$ and $\rho$ contributed significantly to the enhancement in $ZT$. The obtained $ZT$ value is as high as the highest reported values, as shown in Fig. 4, even though the report showed very low density, from which low $\kappa_{ph}$ was obtained, and no experimental value of the specific heat capacity was reported. It is noteworthy that the enhanced $ZT$ value was achieved with high density (over 97%), which means AgSbTe$_2$ has a range of possible applications.

Summary. We developed Ce-doped AgSbTe$_2$ compounds that exhibit enhanced TE performance. The addition of Ce influenced the formation of the heterophase Ag$_2$Te in the AgSbTe$_2$ matrix. We used a variety of methods to confirm that the proportion of Ag$_2$Te was reduced as Ce was added. The change in the proportion of Ag$_2$Te with the addition of Ce was thought to be responsible for the variation in the electrical and thermal properties. We obtained reduced $\rho$ and $\kappa$ values. This resulted in a particularly high $ZT = 1.5$ at 673 K within highly densified samples. Hence, the Ce-doped AgSbTe$_2$ has promising practical applications. It is remarkable that both electrical and thermal properties can be optimized by controlling the proportion of heterophases, so that high $ZT$ values can be achieved.

Method

Materials and characterization. The Ce-doped AgSbTe$_2$ compounds were fabricated by a conventional melting, quenching, and hot-pressing method. Each element (Ce, 99.9%; Ag, 99.999%, Sb, 99.999% and Te, 99.999% in purity) was weighed in a glove box with the nominal composition of Ag$_{1-x}$Ce$_x$Sb$_2$Te$_3$ (0.001 $\leq x \leq 0.004$). The admixture of elements was directly loaded into quartz tubes and was sealed under Ar atmosphere. The sealed ampoules were heated to 1233 K for 10 h in a rocking furnace and quenched in ice water. The solidified ingots were crushed, sieved to particles of $<45 \mu m$, and sintered by hot pressing in Ar for 20 min at 683 K with a pressure of 100 MPa. The samples of 12.7 mm in diameter and about 15 mm in height were cut by a diamond wire saw and polished. The real compositions of the sintered samples were examined using inductively coupled plasma (ICP).

The phases of the Ce-doped AgSbTe$_2$ compounds were analyzed with an X-ray diffractometer (x’pert pro, Analytical) using Cu-K$_\alpha$ radiation ($\lambda = 0.15406$ nm). The microstructure and local composition of the ingot were investigated by field-emission scanning electron microscopy (FE-SEM, S-4800, Hitachi) with energy dispersive X-ray spectroscopy (EDS) and field-emission transmission electron microscopy (FE-TEM, Tecnai G$^{2}$F30 S-twin, FEI) using an electron microprobe. The electrical properties were analyzed in terms of the Seebeck coefficient and resistivity measurement system (ZEM-3, ULVAC-RIKO). The thermal diffusivity was measured using the laser flash method (LFA-457, NETZSCH). The heat capacity was obtained using a differential scanning calorimeter (DSC 404 C, NETZSCH). The method of Archimedes was applied to measure the density of samples. Thermal conductivity was calculated from the density ($d$), heat capacity ($C_p$), and thermal diffusivity ($a$), using the equation: $\kappa = d \cdot C_p \cdot a$. The Hall effect measurement, conducted with a magnet of 0.55 T, provided information on the carrier concentration and mobility.

Acknowledgements
This work was supported by the National Research Foundation of Korea (NRF) grant funded by the Korean Government (MSIP) (NRF-2015R1A5A1036133). This work was partially supported by the Korea Institute of Energy Technology Evaluation and Planning (KETEP) and the Ministry of Trade, Industry & Energy (MOTIE) of the Republic of Korea (No. 20162000000910).

Author Contributions
S.-D.P. and B.-S.K. were responsible for project planning. J.K.L performed experiments. J.K.L. and M.-W.O. wrote the paper. B.R., J.E.L., B.K.M, S.-J.J. and H.-W.L. were involved in data analysis and reviewed the manuscript.
