Abstract: We use the conditional luminosity function (CLF) and data from the 2-degree Field Galaxy Redshift Survey (2dFGRS) to constrain the average relation between light and mass in a Lambda cold dark matter (ΛCDM) cosmology with Ωm = 0.23 and 8 = 0.74 (hereafter WMAP3 cosmology). Reproducing the observed luminosity dependence of the galaxy two-point correlation function results in average mass-to-light ratios that are 35 per cent lower than those in a ΛCDM cosmology with Ωm = 0.3 and 8 = 0.9 (hereafter WMAP1 cosmology). This removes an important problem with previous halo occupation models which had a tendency to predict cluster mass-to-light ratios that were too high. For the WMAP3 cosmology, our model yields average mass-to-light ratios, central galaxy luminosities, halo occupation numbers, satellite fractions and luminosity-gap statistics, that are all in excellent agreement with those obtained from a 2dFGRS group catalogue and from other independent studies. We also use our CLF model to compute the probability distribution P(M | Lcen), that a central galaxy of luminosity Lcen resides in a halo of mass M. We find this distribution to be much broader than what is typically assumed in halo occupation distribution models, which has important implications for the interpretation of satellite kinematics and galaxy-galaxy lensing data. Finally, reproducing the luminosity dependence of the pairwise peculiar velocity dispersions in the 2dFGRS requires relatively low mass-to-light ratios for clusters and a satellite fraction that decreases strongly with increasing luminosity. This is only marginally consistent with the constraints obtained from the luminosity dependence of the galaxy two-point correlation function. We argue that a cosmology with parameters between those of the WMAP1 and WMAP3 cosmologies is likely to yield results with a higher level of consistency.

ABSTRACT
We use the conditional luminosity function (CLF) and data from the 2-degree Field Galaxy Redshift Survey (2dFGRS) to constrain the average relation between light and mass in a Lambda cold dark matter ($\Lambda$CDM) cosmology with $\Omega_m = 0.23$ and $\sigma_8 = 0.74$ (hereafter WMAP3 cosmology). Reproducing the observed luminosity dependence of the galaxy two-point correlation function results in average mass-to-light ratios that are $\sim 35$ per cent lower than those in a $\Lambda$CDM cosmology with $\Omega_m = 0.3$ and $\sigma_8 = 0.9$ (hereafter WMAP1 cosmology). This removes an important problem with previous halo occupation models which had a tendency to predict cluster mass-to-light ratios that were too high. For the WMAP3 cosmology, our model yields average mass-to-light ratios, central galaxy luminosities, halo occupation numbers, satellite fractions and luminosity-gap statistics, that are all in excellent agreement with those obtained from a 2dFGRS group catalogue and from other independent studies. We also use our CLF model to compute the probability distribution $P(M | L_{\text{cen}})$, that a central galaxy of luminosity $L_{\text{cen}}$ resides in a halo of mass $M$. We find this distribution to be much broader than what is typically assumed in halo occupation distribution models, which has important implications for the interpretation of satellite kinematics and galaxy–galaxy lensing data. Finally, reproducing the luminosity dependence of the pairwise peculiar velocity dispersions in the 2dFGRS requires relatively low mass-to-light ratios for clusters and a satellite fraction that decreases strongly with increasing luminosity. This is only marginally consistent with the constraints obtained from the luminosity dependence of the galaxy two-point correlation function. We argue that a cosmology with parameters between those of the WMAP1 and WMAP3 cosmologies is likely to yield results with a higher level of consistency.

1 INTRODUCTION

Using the observed distribution of galaxies to constrain the cosmology-dependent matter distribution requires a detailed knowledge of galaxy bias. The development of the halo model (see Cooray & Sheth 2002, for a detailed review), in which the matter distribution is interpreted in terms of its halo building blocks, has provided us with a convenient way to quantify galaxy bias. The concept is that all galaxies reside in dark matter haloes, and that these haloes themselves are a biased tracer of the dark matter mass distribution, the so-called halo bias. As a consequence of the hierarchical nature of structure formation, more massive haloes are more strongly clustered (Cole & Kaiser 1989; Mo & White 1996, 2002), and the halo bias is thus an increasing function of halo mass. Galaxy bias is then completely specified by a description of how galaxies of different properties are distributed over dark matter haloes of different masses.

In the standard halo occupation models, one tries to constrain the halo occupation distribution (HOD) $P(N | M)$, which expresses the conditional probability that a halo of mass $M$ contains $N$ galaxies (of a specified type). The first moment of this distribution function, $\langle N \rangle_M$, expresses the average number of galaxies as function of halo mass. Together with the halo bias $b_h(M)$, this completely specifies the galaxy bias on large scales. On smaller scales, however, additional information is required, such as the second moment of the HOD, $\langle N(N - 1) \rangle_M$, and information regarding the spatial distribution of galaxies within individual haloes (e.g. Seljak

Numerous studies have shown that the observed two-point correlation function (2PCF) of galaxies tightly constrains the first and second moments of $P(N|M)$ (e.g. Jing, Mo & Börner 1998; Peacock & Smith 2000; Magliocchetti & Porciani 2003; Scranton 2003; Zehavi et al. 2004, 2005; Collister & Lahav 2005; Tinker et al. 2005), and that the resulting constraints are in good agreement with the occupation statistics of dark matter subhaloes (e.g. Kravtsov et al. 2004; van den Bosch, Tormen & Giocoli 2005b). The HOD modelling has also been applied to various galaxy populations at medium to high redshifts (e.g. Bullock, Wechsler & Somerville 2002; Zheng 2004a; Lee et al. 2006; Phleps et al. 2006) as well as to quasars (Porciani, Magliocchetti & Norberg 2004). Furthermore, Zheng & Weinberg (2005) have shown that cosmology and galaxy bias are not degenerate. This means that one cannot arbitrarily modify the HOD and fit the observed clustering of galaxies for any cosmology; the HOD technique can simultaneously constrain both the galaxy bias and cosmology (see also Zheng et al. 2002; van den Bosch, Mo & Yang 2003b; Abazajian et al. 2005).

Since we know that galaxy bias is a function of galaxy properties, such as luminosity and colour, a natural extension of the HOD modelling is to consider the occupation statistics as a function of galaxy properties. In Yang, Mo & van den Bosch (2003), we took a first step in this direction and introduced the conditional luminosity function (hereafter CLF). The CLF, $\Phi(L|M) dL$, gives the average number of galaxies with luminosity $L \pm dL/2$ that reside in a halo of mass $M$. Integrating the CLF over a given luminosity range $[L_1, L_2]$, yields the average number of galaxies with $L_1 \leq L \leq L_2$ that reside in a halo of mass $M$:

$$\langle N \rangle_M = \int_{L_1}^{L_2} \Phi(L|M) dL.$$  

Thus, the CLF contains the same information as the first moment of the HOD $P(N|M)$, but it does so for any luminosity interval. In addition, the CLF also specifies the total, average luminosity in a halo of mass $M$,

$$\langle L \rangle_M = \int_0^\infty \Phi(L|M) L dL,$$

and thus specifies the average relation between light and mass in the Universe. As shown in Yang et al. (2003), the CLF is tightly constrained by the observed luminosity function and the correlation lengths of the galaxy population as function of luminosity. In subsequent papers, the CLF has been used to study the occupation statistics as function of both luminosity and galaxy type at low redshift (van den Bosch, Yang & Mo 2003a; Cooray 2005a, 2006; Yang et al. 2005b) and high redshift (Yan, Madgwick & White 2003; Cooray 2005b, 2006), to study the environment dependence of the galaxy luminosity function (Mo et al. 2004), to constrain cosmological parameters (van den Bosch et al. 2003b; Tinker et al. 2005), to study the pairwise peculiar velocity dispersion (PVD) of galaxies (Jing & Börner 2004; Yang et al. 2004; Li et al. 2006), to construct detailed mock galaxy redshift surveys (MGRSs) (Yan, White & Coil 2004; Yang et al. 2004; van den Bosch et al. 2005a) and to investigate the luminosity and type dependence of the three-point correlation function (Wang et al. 2004). In addition, the CLF has proven a useful aid for interpreting the kinematics of satellite galaxies (van den Bosch et al. 2004), for constructing galaxy group catalogues (Yang et al. 2005a, hereafter YMBJ), and for furthering our understanding of the galaxy luminosity function (Cooray & Milosavljevic 2005).

Clearly, the CLF formalism is a powerful, statistical tool that has many applications. However, the occupation statistics inferred from the observed clustering data are cosmology dependent. Virtually all studies mentioned above have adopted a Lambda cold dark matter ($\Lambda$CDM) concordance cosmology with a matter density $\Omega_m = 0.3$ and a Harrison–Zel’dovich, initial power spectrum with a normalization $\sigma_8 = 0.9$. Recently, however, the 3-yr cosmic microwave background (CMB) data of the Wilkinson Microwave Anisotropy Probe (WMAP) mission (Hinshaw et al. 2006; Page et al. 2006) have argued in favour of a flat $\Lambda$CDM cosmology with a significantly reduced $\Omega_m$ and $\sigma_8$, and with a spectral index that is significantly smaller than unity (Spergel et al. 2006). This has a non-negligible impact on the halo mass function and the halo bias, both of which play an important role in the HOD modelling. The purpose of this paper is to revisit some of our conclusions based on the CLF formalism in the revised concordance cosmology. In particular, we want to investigate (i) whether we can still simultaneously fit the galaxy LF and the luminosity dependence of the galaxy correlation length, (ii) what this implies for the average relation between light and mass in the Universe and (iii) whether the resulting CLF is consistent with a range of other observations, including various occupation statistics inferred from galaxy group catalogues, the luminosity dependence of the PVDs, and the satellite fractions inferred from galaxy–galaxy lensing studies. Finally, we improve upon our previous analysis by taking account of the scale dependence of the halo bias, and by properly modelling the observational data over the light-cone.

This paper is organized as follows. In Section 2, we describe the theoretical framework of the CLF formalism, including a description of modelling on the light-cone, and we discuss how small changes in cosmological parameters impact on various statistics of dark matter haloes. Section 3 presents the new CLF for the new WMAP concordance cosmology, and compares the mass-to-light ratios, satellite fractions and the luminosity gap statistic predicted by that model to observational data. Section 4 presents a detailed analysis of the halo occupation numbers predicted by our CLF model, which are compared to other HOD models. In Section 5, we use MGRSs to study the PVDs of galaxies and their luminosity dependence. We summarize our results in Section 6. Throughout this paper log represents the 10-based logarithm, while In represents the natural logarithm.

## 2 THEORETICAL FRAMEWORK

### 2.1 Light-cone modelling

As shown in Yang et al. (2003), the CLF can be tightly constrained by fitting it to the galaxy luminosity function, $\Phi(L)$, and to the galaxy correlation lengths as function of luminosity, $r_0(L)$. A complication arises from the fact that these observational data have been determined on a light-cone. In particular, each data point typically derives from a different light-cone specified by different redshift limits $z_{\text{min}}$ and $z_{\text{max}}$. For example, in a flux-limited sample, one has that $z_{\text{max}} = z_{\text{max}}(L)$.

Since the halo mass function and the halo bias are both functions of redshift, one needs to properly integrate the model over the light-cone before comparing it to the data. This becomes more and more important when $z_{\text{max}} \gg z_{\text{min}}$. However, even for relatively nearby surveys, such as the 2-degree Field Galaxy Redshift Survey (2dFGRS) considered in this paper, ignoring this light-cone modelling results in $\Phi(L)$ and $r_0(L)$, for the same CLF model, that are different.
by 5–15 per cent (typically the errors are larger for brighter samples, since they cover a larger volume). Since this is smaller than, or comparable to, the errors on the data, the light-cone modelling only has a very marginal effect on the results presented here. However, it cannot be ignored in future data sets that cover a larger redshift range; the method outlined below illustrates how one can take the light-cone effects into account.

Within the CLF formalism, the light-cone integrated LF is given by

$$\Phi(L) = \frac{1}{V} \int_{z_{\min}}^{z_{\max}} dz \frac{dV}{dz} \int_0^\infty dM \, \Phi(L|M,z) n(M,z),$$

where $dV/dz$ is the comoving volume element per unit solid angle. In what follows we will assume that the CLF does not evolve with redshift, i.e. $\Phi(L|M,z) = \Phi(L|M)$, which implies that we can write

$$\Phi(L) = \int_0^\infty \Phi(L|M) n_{\text{eff}}(M) dM$$

with

$$n_{\text{eff}}(M) = \frac{1}{V} \int_{z_{\min}}^{z_{\max}} dz \frac{dV}{dz} n(M,z).$$

Note that this effective mass function is different for each data point, i.e. for each different $(z_{\min}, z_{\max})$. Although the assumption that the CLF does not evolve with redshift is likely to be an oversimplification, it should not have a significant impact on our results. After all, the data used to constrain our models are restricted to $0.02 \leq z \leq 0.15$. As discussed above, for this small redshift range the light-cone modelling has an almost negligible effect on our model parameters, and it is unlikely that $\Phi(L|M)$ will have evolved much over this small redshift interval. In the case of the clustering data, we can proceed as follows. At a given redshift, and on large scales, the 2PCF for dark matter haloes of mass $M$ can be defined as

$$\xi_{\text{halo}}(r, M, z) = b_h^2(M, r, z) \xi_{\text{dm}}(r, z)$$

with $b_h(M, r, z)$ being the scale-dependent halo bias and $\xi_{\text{dm}}(r, z)$ being the evolved, non-linear correlation function of the dark matter at redshift $z$. In what follows we assume (i) that the mass dependence of the halo bias is separable from the scale dependence and (ii) that the scale-dependent part is independent of redshift. We thus write that

$$b_h^2(M, r, z) = b_h^2(M, z) \xi(r).$$

Using large numerical simulations Tinker et al. (2005) have shown that assumption (i) is accurate and that, at $z = 0$,

$$\xi(r) = \frac{[1 + 1.17 \xi_{\text{dm}}(r, 0)]^{1.49}}{[1 + 0.69 \xi_{\text{dm}}(r, 0)]^{2.09}}.$$

Our assumption (ii) implies that this equation also holds at $z > 0$. Although this is untested at present, and may well be incorrect, it is unlikely to have a significant effect on our results. After all, the correction for the scale dependence of the halo bias is only important for $r \lesssim 3 h^{-1}$ Mpc, which is smaller than the scales probed here. Indeed, if we completely ignore the scale dependence (i.e. if we set $\xi = 1$), we obtain results that are only $\sim 5$ per cent different, which is smaller than the measurements errors.

The mass and redshift dependence of the halo bias can be written as

$$b_h(M, z) = 1 + \frac{1}{\sqrt{a \delta_c(z)}} \left[ \sqrt{a} (\alpha_v^2) + \sqrt{b} (\alpha_v^2)^{1-c} - (\alpha_v^2)^{c} + b (1 - c)(1 - c/2) \right],$$

with $a = 0.707$, $b = 0.5$, $c = 0.6$ and $\nu = \nu(M, z) = \delta_c(z)/\sigma(M)$ (Sheth, Mo & Tormen 2001). Here $\delta_c(z)$ is the critical overdensity required for spherical collapse at redshift $z$, and $\sigma(M)$ is the linear theory rms mass fluctuation on the mass scale $M$. Tinker et al. (2005), using state-of-the-art numerical simulations, reinvestigated the mass dependence of the halo bias, and found that equation (9) accurately fits their simulations, but with $b = 0.35$ and $c = 0.80$, which are the values we adopt throughout.

The 2PCF for dark matter haloes of mass $M$ in the volume of a light-cone with $z_{\min} \leq z \leq z_{\max}$ is given by

$$\xi_{\text{halo}}(r, M) = \int_{z_{\min}}^{z_{\max}} dz \frac{dV}{dz} n^2(M,Z) d^2 \xi_{\text{halo}}(r, M)$$

(cf. Hamana et al. 2001). Using that, on sufficiently large (linear) scales, $\xi_{\text{dm}}(r, z) = D^2(z) \xi_{\text{dm}}(r, 0)$, with $D(z)$ linear growth rate normalized to unity at $z = 0$, we obtain that

$$b_h^2(M, r, z) = b_h^2(M) \xi(r) \xi_{\text{dm}}(r, 0)$$

with

$$b_h^2(M) = \frac{\int_{z_{\min}}^{z_{\max}} dz \frac{dV}{dz} n^2(M,Z) d^2 \xi_{\text{halo}}(r, M)}{\int_{z_{\min}}^{z_{\max}} dz \frac{dV}{dz} n^2(M,Z)}.$$

Using this effective halo bias, we can write the 2PCF for galaxies of luminosity $L$, on large scales, as

$$\xi_{\text{galaxy}}(r, L) = b_g^2(M) \xi(r) \xi_{\text{dm}}(r, 0),$$

where the effective galaxy bias $b_g(M, r, z)$ is related to the effective halo bias, the effective halo mass function, and the CLF according to

$$b_g^2(L) = \frac{1}{\Phi(L)} \int_0^\infty \Phi(L|M) b_h(M, r) n_{\text{eff}}(M) dM.$$

### 2.2 Cosmology

From the above it is clear that the computation of the galaxy correlation lengths, $r_L(L)$, defined by $\xi_{\text{galaxy}}(r, L) = 1$, requires the halo mass function, $n(M, z)$, the halo bias function, $b_h(M, z)$, and the dark matter correlation function, $\xi_{\text{dm}}(r, z)$, all of which are cosmology-dependent. In this paper, we focus on a flat ΛCDM cosmology with a matter density $\Omega_m = 0.238$, a baryonic matter density $\Omega_b = 0.041$, a Hubble parameter $h = H_0/(100 \text{ km s}^{-1} \text{ Mpc}^{-1}) = 0.734$, a power-law initial power spectrum with spectral index $n_s = 0.951$ and a normalization $\sigma_8 = 0.744$. These are the parameters that best fit the 3-yr WMAP data (Spergel et al. 2006), and we will refer to this cosmology in what follows as the WMAP3 cosmology. For comparison, we also compare some of our results to a flat ΛCDM cosmology with $\Omega_m = 0.3$, $\Omega_b = 0.04$, $h = 0.7$, $n_s = 1.0$ and $\sigma_8 = 0.9$. With strong support from the first year data release of the WMAP mission, this model has been considered the ‘concordance’ cosmology in the vast majority of all HOD studies. In what follows we will refer to a cosmology with these parameters as the WMAP1 cosmology.

Throughout this paper, we compute the halo mass function using the form suggested by Sheth et al. (2001), which has been shown to be in excellent agreement with numerical simulations as long as halo masses are defined as the masses inside a sphere with an average overdensity of 180 (Jing 1998; Sheth & Tormen 1999; Jenkins et al. 2001; White 2002). Therefore, in what follows we consistently use that definition of halo mass when referring to $M$. The linear power spectrum of density perturbations is computed using the transfer
function of Eisenstein & Hu (1998), which properly accounts for the baryons, while the evolved, non-linear power spectrum, required to compute the dark matter correlation function, is computed using the fitting formula of Smith et al. (2003).

The left-hand panel of Fig. 1 plots the halo mass functions at \( z = 0 \) for the WMAP1 and WMAP3 cosmologies. Note that the new concordance cosmology predicts much fewer massive haloes: in fact, the number density of haloes with \( M = 10^{15} \, h^{-1} \, M_\odot (10^{14} h^{-1} M_\odot) \) is only 19 per cent (48 per cent) of what it is in the WMAP1 cosmology. Clearly, all galaxies assigned to these haloes in the WMAP1 HOD models now have to be redistributed over other haloes. The middle panel of Fig. 1 plots the halo bias at \( z = 0 \) as function of halo mass. Although the overall clustering strength of the dark matter is reduced in the WMAP3 cosmology with respect to that in the WMAP1 cosmology (see Table 1), the halo bias has become larger. The difference is largest at \( M \simeq 3 \times 10^{14} h^{-1} \, M_\odot \), where the halo bias is \( \sim 1.5 \) times larger than that in the WMAP1 cosmology.

As mentioned above, our halo masses \( M \) are defined as the masses inside a sphere with an average overdensity of 180. Another definition of halo mass that is often adopted is the so-called virial mass, \( M_{\text{vir}} \), which indicates the mass inside a sphere with an average density equal to \( \Delta_{\text{vir}} \) times the critical density for closure. The value of \( \Delta_{\text{vir}} \) follows from the solution to the collapse of a spherical top-hat perturbation under the assumption that the halo has just virialized, and depends on cosmology through \( \Omega_m(z) \) (Peebles 1980; see Bryan & Norman 1998 for a useful fitting function). Under the assumption that the density distribution of dark matter haloes is well fit by a NFW profile (Navarro, Frenk & White 1997), one can convert \( M \) to \( M_{\text{vir}} \) (and vice versa) as long as one knows the halo concentration parameter \( c_{\text{vir}} \). Using the \( c_{\text{vir}}(M_{\text{vir}}) \) of Macciò et al. (2006), we find that the relation between \( M \) and \( M_{\text{vir}} \) is accurately fit (to better than 1 per cent over the mass range \( 10^8 \leq M \leq 10^{16} h^{-1} M_\odot \)) by

\[
\log \left[ \frac{M_{\text{vir}}}{10^{12} h^{-1} M_\odot} \right] = a_0 + a_1 y + a_2 y^2
\]

with \( y = \log[M/10^{12} h^{-1} M_\odot] \). Over the same mass range, the relation between \( c_{\text{vir}} \) and \( M \) (not \( M_{\text{vir}} \)) is accurately fit by

\[
c_{\text{vir}} = c_0 + c_1 y + c_2 y^2.
\]

The best-fitting parameters \( a_i \) and \( c_i \) \((i = 0, 1, 2)\), for both the WMAP1 and the WMAP3 cosmologies, are listed in Table 1. The resulting \( c_{\text{vir}}(M) \) are shown in the right-hand panel of Fig. 1: in the WMAP3 cosmology halo concentrations are \( \sim 30 \) per cent smaller than those in the WMAP1 cosmology. This may have a non-negligible impact on the 2PCF on small scales \( (r \lesssim 50 h^{-1} \text{kpc}) \). In addition, this reduction in halo concentrations also has important implications for the Tully–Fisher zero-point (see discussions in van den Bosch et al. 2003b and Dutton et al. 2007).

Notes. Parameters of the two cosmological models discussed in this paper. Column (1) indicates the name by which we refer to these cosmologies in the paper. Columns (2)–(7) list the matter density, the energy density associated with the cosmological constant, the baryon density, the Hubble parameter, the spectral index and the power-spectrum normalization. Column (8) lists the characteristic halo mass (in \( h^{-1} M_\odot \)), defined as the mass scale at which the mass variance \( \sigma(M) = 1.68 \). Column (9) lists the correlation length (in \( h^{-1} \text{Mpc} \)) of the evolved, non-linear matter field at \( z = 0 \). Finally, Columns (10)–(15) list the fitting parameters that describe the relation between \( M \) and \( M_{\text{vir}} \) (equation 15), and between halo concentration \( c_{\text{vir}} \) and \( M \) (equation 16).
This parametrization has four free parameters: a characteristic mass $M_*$, for which the mass-to-light ratio is equal to $(M/L)_1$, and two slopes, $\gamma_1$ and $\gamma_2$, that specify the behaviour of $\langle M/L\rangle$ at the low- and high-mass ends, respectively.

A similar parametrization is used for the characteristic luminosity $\tilde{L}^* (M)$:

$$\frac{M}{\tilde{L}^* (M)} = \frac{1}{2} \left( \frac{M}{L} \right) f(\tilde{\alpha}) \left[ \left( \frac{M}{M_1^*} \right)^{\gamma_1} + \left( \frac{M}{M_2^*} \right)^{\gamma_2} \right],$$

with

$$f(\tilde{\alpha}) = \frac{\Gamma(\tilde{\alpha} + 2)}{\Gamma(\tilde{\alpha} + 1, 1)}.$$  

Here $\Gamma(x)$ is the Gamma function and $\Gamma(a, x)$ is the incomplete Gamma function. This parametrization has two additional free parameters: a characteristic mass $M_1$ and a power-law slope $\gamma_2$. In our previous CLF studies, we used to set $\langle M/L\rangle_m = (M/L)_1$ for haloes with $M \geq 10^{14} h^{-1} M_\odot$, with $(M/L)_1$ being a free parameter that describes the average mass-to-light ratio of clusters. This was motivated by a number of observational studies (Bahcall, Lubin & Dorman 1995; Bahcall et al. 2000; Sanderson & Ponman 2003), which indicated that $(M/L)_1$ is roughly constant on the scale of galaxy clusters. This was further supported by semi-analytical models of galaxy formation, which revealed a similar behaviour (see fig. 14 in van den Bosch et al. 2003a). However, a number of studies have suggested that the average mass-to-light ratio of clusters continues to increase with mass (Adami et al. 1998; Bahcall & Comerford 2002; Girardi et al. 2002; Marinoni & Hudson 2002; Lin, Mohr & Stanford 2003, 2004; Ramella et al. 2003; Rines et al. 2004; Vale & Ostriker 2004, 2006; Popesso et al. 2005). Especially the more recent studies have convincingly shown that $(M/L)_1 \propto M^{0.24 \pm 0.08}$ on the scale of clusters, virtually independent of the photometric band in which the luminosities are measured (Popesso et al. 2005, and references therein). In this paper, we therefore do not force $(M/L)_1$ to become constant at large $M$. Rather we simply adhere to the functional form of equation (18), according to which $\langle M/L\rangle_m \propto M^{\gamma_1}$ at large $M$. As we will show below, this actually yields values for $\gamma_2$ that are in excellent agreement with the cluster data discussed above. In order to allow for a comparison with our previous models, we define $(M/L)_1$ as the mass-to-light ratio for haloes with $M = 10^{14} h^{-1} M_\odot$.

For $\tilde{\alpha}(M)$, we adopt a simple linear function of $\log(M)$,

$$\tilde{\alpha}(M) = \alpha_{15} + \eta \log(M/15).$$

with $M_{15}$ being the halo mass in units of $10^{15} h^{-1} M_\odot$, $\alpha_{15} = \tilde{\alpha}(M_{15}) = 1$ and $\eta$ describes the change of the faint-end slope $\tilde{\alpha}$ with halo mass. Note that once $\tilde{\alpha}$ and $\tilde{L}^*$ are given, the normalization $\Phi^*$ of the CLF is obtained through equation (18), using the fact that the total (average) luminosity in a halo of mass $M$ is given by

$$\langle L \rangle_m = \int_0^\infty \Phi(L | M) dL = \tilde{\Phi}^* \tilde{L}^* \Gamma(\tilde{\alpha} + 2).$$

Finally, we introduce the mass scale $M_{\text{min}}$ below which we set the CLF to zero; i.e., we assume that no stars form inside haloes with $M < M_{\text{min}}$. Motivated by reionization considerations (see Yang et al. 2003 for details), we adopt $M_{\text{min}} = 10^9 h^{-1} M_\odot$ throughout. Note, however, that this lower mass limit does not significantly influence our results. Changing $M_{\text{min}}$ to $10^7$ or $10^{10} h^{-1} M_\odot$ has only a very modest impact on the results presented below.

As we will show below, this Schechter-function parametrization of the CLF yields good fits to the data. In addition, using galaxy group catalogues, Yang et al. (2005b) have shown that the Schechter form is also consistent with direct observations of the CLF in the $b_1$ band. On the other hand, the analysis of the luminosity functions of clusters and groups by Hansen et al. (2005) suggests that on group-scales the $r$-band CLF is not well-fitted by a Schechter function (except when the brightest cluster galaxy is removed). A similar deviation was found by Zheng et al. (2005) for the conditional stellar mass function in semi-analytical models. However, the $g$-band CLF in their models has a form that is very similar to a Schechter function. We therefore believe that our assumption of a Schechter-function form for the CLF is appropriate for the $b_1$ band used here. However, we emphasize that it is important to keep an open mind for alternative functional forms (see for example Cooray 2005a, 2006; Cooray & Milosavljević 2005; Zheng et al. 2005).

### 2.4 Centrals and satellites

The CLF parametrization presented above does not distinguish a priori between central and satellite galaxies. This is somewhat unfortunate, as there are good reasons to treat these kinds of galaxies separately (see Zheng et al. 2005, and references therein). Although it is straightforward to devise CLF parametrizations with a natural, a priori split in central and satellite galaxies (e.g. Cooray 2005a, 2006; Cooray & Milosavljević 2005), we stick to our Schechter-function parametrization and apply a posteriori split into central and satellite components. In particular, we assume that the central galaxy is always the brightest galaxy in a halo.

Following van den Bosch et al. (2004) we write the conditional probability distribution $P(L_{\text{cen}} | M) dL_{\text{cen}}$, with $L_{\text{cen}}$ being the luminosity of the central galaxy, as the product of the CLF and a new function $f(L_{\text{cen}}, M)$ which depends on how galaxy luminosities are ‘drawn’ from the CLF:

$$P(L_{\text{cen}} \mid M) dL_{\text{cen}} = \Phi(L_{\text{cen}} | M) f(L_{\text{cen}}, M) dL_{\text{cen}}.$$  

Since the CLF only gives the average number of galaxies with luminosities in the range $L \pm dL/2$ in a halo of mass $M$, there are many different ways in which one can assign luminosities to the $N_i$ galaxies of halo $i$ and yet be consistent with the CLF. The simplest approach would be to simply draw $N_i$ luminosities from $\Phi(L | M)$ and to associate $L_{\text{cen}}$ with the luminosity of the brightest galaxy. We refer to this luminosity sampling as ‘random’, which results in the broadest $P(L_{\text{cen}} | M)$ possible, at least when we adhere to the assumption that the central galaxy is the brightest halo galaxy.

Alternatively, one could use a more constrained approach, and, for instance, assume that the luminosity of the brightest (and hence central) galaxy is always larger than $L_1$, defined by

$$\int_{L_1}^\infty \Phi(L | M) dL \equiv 1.$$  

Although $L_1 = L_1(M)$ is defined such that a halo has on average one galaxy with $L \geq L_1$, demanding that $L_{\text{cen}} \geq L_1$ is equivalent to assuming that galaxy formation is somewhat deterministic and that the number of galaxies with $L \geq L_1(M)$ is always exactly 1. Hereafter we will refer to this sampling method as ‘deterministic’, which yields the narrowest $P(L_{\text{cen}} | M)$ possible.

In the case of ‘deterministic’ drawing, one obviously has that

$$f(L_{\text{cen}}, M) = \begin{cases} 1 & \text{if } L_{\text{cen}} \geq L_1(M) \\ 0 & \text{if } L_{\text{cen}} < L_1(M) \end{cases}$$

\[\text{Equation 25}\]
so that the expectation value for the luminosity of a central galaxy in a halo of mass $M$ is simply given by

$$
(L_{\text{cen}})_M = \int_{L_1}^{L_\infty} \Phi(L \mid M) \, dL = \Phi^* \sum_{i=1}^{L_1} \frac{L_i}{L_i^*} \Gamma(a + 2, L_i/L_i^*).
$$

(26)

In the case of ‘random’ drawing, one obtains that

$$
f(L_{\text{cen}}, M) = \left(1 - \frac{\xi}{\langle N \rangle_M} \right) \exp(-\xi)
$$

(27)

with

$$
\xi = \frac{\langle N \rangle_M - 1}{\langle N \rangle_M} \int_{L_{\text{cen}}}^{\infty} \Phi(L \mid M) \, dL
$$

(28)

(see appendix B in van den Bosch et al. 2004 for a derivation), and the expectation value for $L_{\text{cen}}$ has to be computed numerically.

Unless specifically stated otherwise, in what follows we adopt the ‘deterministic’ sampling strategy because it allows various statistics of centrals and satellites to be computed analytically from the CLF. Most of the results do not significantly depend on this particular choice. Whenever the detailed form of $f(L_{\text{cen}}, M)$ is important, we will present the results for both the ‘deterministic’ and the ‘random’ samplings.

### 2.5 Parameter fitting

The CLF, as specified above, has a total of eight free parameters: two characteristic masses $M_1$ and $M_2$, four parameters that describe the various mass dependences $\gamma_1$, $\gamma_2$, $\gamma_3$, and $\eta$, a normalization for the mass-to-light ratio, $(M/L)_0$, and a normalization of the faint-end slope, $\alpha_{15}$. The data that we use to constrain the CLF consist of the 2dFGRS luminosity function of Madgwick et al. (2002) and the galaxy–galaxy correlation lengths as function of luminosity obtained from the 2dFGRS by Norberg et al. (2002).

The LF of Madgwick et al. (2002) has been determined using the 2dFGRS data over the redshift range $0.01 \leq z \leq 0.15$, which we model using equations (4) and (5), with $z_{\text{min}} = 0.01$ and $z_{\text{max}} = \text{MIN}[0.15, z_{\text{lim}}(L_1)]$. Here $z_{\text{lim}}(L_1)$ is the redshift at which the apparent magnitude of a galaxy of luminosity $L$ is equal to the flux limit of the 2dFGRS, $b_1 = 19.3$ (Colless et al. 2001).

Norberg et al. (2002) defined a set of eight volume-limited samples, each defined by two luminosity limits, $L_{\text{min}}$ and $L_{\text{max}}$, and two redshift limits, $z_{\text{min}}$ and $z_{\text{max}}$. For each of these samples, they determined the correlation length, $r_0$, defined by $\xi_{\text{gg}}(r_0) = 1$. We model this using equation (13) with

$$
b_{\text{gg}} = \int_0^\infty \frac{(N)_M b_{\text{eff}}(M) n_{\text{eff}}(M) \, dM}{\int_0^\infty (N)_M n_{\text{eff}}(M) \, dM},
$$

(29)

where $(N)_M$ is given by (1), but with $L_1$ and $L_2$ replaced by the luminosity limits $L_{\text{min}}$ and $L_{\text{max}}$ of the volume-limited sample under consideration.

To determine the likelihood function of our free parameters, we use the Monte Carlo Markov Chain (hereafter MCMC) technique (see e.g. Gamerman 1997). Each element of the chain is a model, consisting of eight parameters. At any point in the chain, we generate a new trial model by drawing the shifts in the eight free parameters from eight independent Gaussian distributions, centred on the current value of the corresponding model parameter. The probability of accepting the trial model is

$$
P_{\text{accept}} = \begin{cases} 1.0 & \text{if } \chi^2_{\text{new}} < \chi^2_{\text{old}} \\ \exp[-(\chi^2_{\text{new}} - \chi^2_{\text{old}})/2] & \text{if } \chi^2_{\text{new}} \geq \chi^2_{\text{old}} \end{cases}.
$$

(30)

Here $\chi^2 = \chi^2_{\phi} + \chi^2_{x_0}$ with

$$
\chi^2_{\phi} = \sum_{i=1}^{N_\phi} \left[ \frac{\Phi(L_i) - \hat{\Phi}(L_i)}{\Delta \Phi(L_i)} \right]^2,
$$

(31)

and

$$
\chi^2_{x_0} = \sum_{i=1}^{N_{x_0}} \left[ \frac{\xi_{\text{gg}}(r_0_i) - 1}{\Delta \xi_{\text{gg}}(r_0_i)} \right]^2,
$$

(32)

where $\xi$ indicates an observed quantity, and $N_\phi = 35$ and $N_{x_0} = 8$ are the number of data points for the LF and the correlation lengths, respectively. Note that the correlation lengths for different luminosity ranges are not independent. Although the level of covariance is likely to be small, since Norberg et al. (2002) used volume-limited samples, we caution that these $\chi^2$ values should only be regarded as estimates.

### 2.6 The model

Using the method described above, we construct two chains consisting of 20 million models each, one for the WMAP1 cosmology and another for the WMAP3 cosmology. Each chain is thinned by a factor of $10^3$ to remove the correlations between neighbouring models (see van den Bosch et al. 2005a, for details). The end results are two MCMCs consisting of 2000 independent models each that properly sample the full posterior distributions.

Fig. 2 shows that the model based on the WMAP3 cosmology accurately fits the galaxy LF and the galaxy correlation lengths as function of luminosity. The WMAP1 cosmology, however, yields an equally good fit to the data (not shown here, but see fig. 3 in van den Bosch et al. 2005a). The fact that both cosmologies allow an equally good fit to these data, despite the large differences in halo mass function and halo bias, illustrates that $\Phi(L)$ and $r_0(L)$ alone allow a fair amount of freedom in cosmological parameters (cf. van den Bosch et al. 2003b). However, as we will see below, the WMAP1 and WMAP3 cosmologies predict significantly different mass-to-light ratios.

Fig. 3 plots the posterior distributions of the CLF parameters for both the WMAP1 (red, unshaded histograms) and the WMAP3 (blue shaded histograms) MCMCs. The median and 68 per cent confidence intervals of these distributions are listed in Table 2. A comparison of the WMAP1 results presented here with those presented in van den Bosch et al. (2005a) shows small differences (all within the 68 per cent confidence levels). These owe to the fact that (i) we use a new model for the halo bias, including its scale dependence, (ii) we properly model the data over its light-cone and (iii) we no longer impose the constraint that the mass-to-light ratio is constant for haloes with $M \geq 10^{14} h^{-1} M_{\odot}$. Of these, (i) is by far the most important.

Comparing the WMAP1 and WMAP3 results, one notes that several parameters, notably $M_2$, $\alpha_{15}$, $\eta$, $\gamma_3$, and $\gamma_2$, have virtually the same likelihood distributions for both cosmologies. In the case of $(M/L)_0$, $(M/L)_1$, and $M_1$, however, the distributions for the WMAP1 and WMAP3 cosmologies are clearly offset from each other. As we show below in more detail, this mainly reflects the fact that the mass-to-light ratios predicted for the WMAP3 cosmology are significantly lower than those for the WMAP1 cosmology.

1 Note that, by definition, $\xi_{\text{gg}}(r_0_i) = 1$.

Halo occupation statistics

Figure 2. The data used to constrain the models (symbols plus errorbars), and the 68 and 95 per cent confidence limits from the WMAP3 MCMC. The left-hand panel shows the galaxy luminosity function with the 2dFGRS data from Madgwick et al. (2002), while the right-hand panel shows the values of the galaxy–galaxy correlation function at the correlation lengths of the magnitude bins used by Norberg et al. (2002). For the data, these are unity by definition. Note that the model accurately fits the data.

Figure 3. Constraints on the nine CLF parameters obtained from our MCMCs. The shaded (blue) and non-shaded (red) histograms correspond to the WMAP3 and WMAP1 cosmologies, respectively. The median and 68 per cent confidence intervals of the distributions are listed in Table 2. Masses and mass-to-light ratios are in units of $h^{-1} M_{\odot}$ and $h (M/L)_{\odot}$, respectively.

3 RESULTS

In what follows we use the MCMC presented above to make a number of predictions regarding the galaxy–dark matter connection. Where possible, we will compare these predictions to the results obtained from an analysis of a large catalogue of galaxy groups selected from the 2dFGRS using the halo-based galaxy group finder of YMBJ. A short description of this group catalogue is presented in Appendix A.

3.1 Mass-to-light ratios

As discussed above, the CLF allows one to compute the average relation between light and mass in the Universe. We present these results in terms of the average mass-to-light ratio as function of halo mass, $(M/L)_{18}$. Here $M$ is defined as the mass within a radius inside of which the average density is 180 times the background density, which can be converted into the virial mass $M_{\text{vir}}$ using equation (15). The quantity $L_{18}$ is the total luminosity in the photometric $b_J$ band.
Table 2. CLF parameters.

| ID     | (M/L)_{\odot} | (M/L)_0 | \log M_1 | \log M_2 | \gamma_1 | \gamma_2 | \gamma_3 | \alpha_{15} | \eta  |
|--------|----------------|---------|----------|----------|----------|----------|----------|-------------|-------|
| WMAP1  | 432^{+92}_{-69} | 129^{+26}_{-19} | 10.88^{+0.20}_{-0.22} | 12.11^{+0.23}_{-0.26} | 2.32^{+1.16}_{-0.83} | 0.27^{+0.07}_{-0.06} | 0.69^{+0.05}_{-0.05} | -1.20^{+0.26}_{-0.26} | -0.25^{+0.09}_{-0.11} |
| WMAP3  | 350^{+94}_{-67} | 89^{+18}_{-13} | 10.70^{+0.25}_{-0.19} | 12.02^{+0.23}_{-0.24} | 2.96^{+1.71}_{-1.05} | 0.27^{+0.07}_{-0.06} | 0.70^{+0.06}_{-0.06} | -1.18^{+0.31}_{-0.32} | -0.24^{+0.12}_{-0.12} |

Notes: Parameters of CLF models. Column (1) lists the ID by which we refer to each CLF in the text. Columns (2)–(10) list the CLF parameters obtained from the MCMCs. The upper two entries indicate the median and 68 per cent confidence levels, the middle two rows list the parameters of the best-fitting models and the lower two rows list the parameters of three extreme models discussed in Section 5. Masses and mass-to-light ratios are in $h^{-1} M_{\odot}$ and $h (M/L)_0$, respectively.

Figure 4. Posterior constraints on a number of quantities computed from the WMAP3 MCMC. The contours show the 68 and 95 per cent confidence limits from the marginalized distributions. Upper left-hand panel: the average ratio between $M$ and $L_{18}$ as a function of halo mass. The (red) solid dots indicate the results from our 2dFGRS group catalogue (see Table A1), while the thick (black) line indicates the results from the 2PGG group catalogue of Eke et al. (2004). Upper right-hand panel: the average relation between $L_{\text{cen}}$ and $M$. Again, the (red) solid dots indicate the results obtained from our 2dFGRS group catalogue. Lower left-hand panel: the faint-end slope of the CLF, $\alpha$, as a function of halo mass $M$. Solid dots (red) and squares (black) correspond to the results obtained from our 2dFGRS group catalogue and the 2PGG catalogue, respectively. Lower right-hand panel: the average satellite fraction as a function of luminosity. Solid circles (red) and triangles (blue) indicate the satellite fractions of early- and late-type galaxies, respectively, obtained by Mandelbaum et al. (2006) from galaxy–galaxy lensing in the SDSS. The thick dashed line corresponds to the results obtained by TNWW from a HOD analysis of the 2dFGRS, and the two thick crosses are the satellite fractions (and their 68 per cent confidence limits) obtained by Cooray (2006) from a CLF analysis of the SDSS.

of all galaxies brighter than $M_{b} - 5 \log h = -18.0$, which is easy to obtain from the CLF.

The upper panels of Fig. 4 show the 68 and 95 per cent confidence limits on $(M/L)_{18}$ and $L_{\text{cen}}(M)$ as obtained from our WMAP3 MCMC discussed above. The particular shape of $(M/L)_{18}$ holds important information regarding galaxy formation. For example, the pronounced minimum at $M \approx 2 \times 10^{11} h^{-1} M_{\odot}$ indicates the mass scale at which galaxy formation is most efficient. At lower masses $(M/L)_{18}$ increases dramatically, indicating that galaxy formation is unable to make galaxies with $M_{b} - 5 \log h \leq -18.0$ in such low-mass haloes. At the high-mass end, the mass-to-light ratio also increases, though less rapidly, indicating that some processes, possibly including active galactic nucleus feedback, cause galaxy formation to also become relatively inefficient in massive haloes.
The solid circles with errorbars correspond to the results obtained from our 2dFGRS group catalogue (Table A1), and are in excellent agreement with the CLF predictions. It is extremely reassuring that two completely different approaches yield average mass-to-light ratios that are in such good agreement. Note that the errorbars indicate the observed scatter, not the error on the mean, and that the group masses are cosmology dependent (see Appendix A for details).

According to our parametrization, at the high-mass end \((M/L)_{M} \propto M^{\alpha}\). We obtain that \(\gamma_{2} = 0.27^{+0.07}_{-0.06}\) (see Table 2), in good agreement with our 2dFGRS galaxy group results and with a wide range of additional studies (see Section 2.3). The solid (black) line, however, indicates the mass-to-light ratios obtained by Eke et al. (2004) from their 2dFGRS group catalogue called 2PIGG (2dFRGS Percollation-Inferred Galaxy Group). Although the agreement with our CLF predictions and with the results from our 2dFGRS group catalogue is good for \(M \leq 10^{14} h^{-1} M_{\odot}\), the 2PIGG catalogue yields that \(\gamma_{2} \rightarrow 0\) for \(M \gtrsim 10^{14} h^{-1} M_{\odot}\). Similar results were obtained by Bahcall et al. (1995, 2000) and Sanderson & Ponman (2003). To test whether the clustering data itself can discriminate between these results, we have constructed a CLF MCMC in which we set \((M/L) = (M/L)_{CL}\), for \(M \geq 10^{14} h^{-1} M_{\odot}\). The resulting model can fit the observed \(\Phi(L)\) and \(r_{0}(L)\) equally well as the model presented here, indicating that the clustering data alone cannot meaningfully constrain the slope of the relation between mass and light on the scale of clusters. The simple fact that two group catalogues constructed from the same data set (2dFGRS) yield predictions that are very different, accentuates the need for more thorough investigations.

A comparison with fig. 3 in van den Bosch et al. (2005a) shows that the mass-to-light ratios predicted by the CLF formalism are significantly lower in the WMAP3 cosmology, compared to those in the WMAP1 cosmology. This difference is most pronounced near the minimum \((M \gtrsim 3 \times 10^{13} h^{-1} M_{\odot})\), where the WMAP1 cosmology predicts mass-to-light ratios that are \(-45\) per cent higher. At the massive end the difference is less pronounced, but at \(M = 10^{14} h^{-1} M_{\odot}\) the WMAP1 mass-to-light ratios are still \(-25\) per cent higher than those for the WMAP3 cosmology. The reason for this change is a rather complicated mix of effects. First of all, in the WMAP3 cosmology there are much fewer massive haloes. Secondly, changing the cosmology from WMAP1 to WMAP3 decreases the dark matter correlation length (see Table 1). Consequently, galaxies have to become more strongly biased in order to match their observed correlation lengths. To some extent, this is automatically achieved by the fact that the halo bias is larger in the WMAP3 cosmology (cf. Fig. 1). However, since the strength of this effect is strongly dependent on halo mass, it is difficult to make intuitive predictions. Our analysis shows that all these effects conspire to cause the average mass-to-light ratios to decrease on all mass scales.

The fact that the average mass-to-light ratios are cosmology dependent is of great importance. As we have shown in van den Bosch et al. (2003b, hereafter BMY03), it allows us to put tight constraints on cosmological parameters, in particular on \(\Omega_{m}\) and \(\sigma_{8}\). In principle, there is a wide range of cosmologies that allow one to accurately fit both \(\Phi(L)\) and \(r_{0}(L)\). Changing the cosmology typically implies a change in the halo bias and in the overall clustering strength of the dark matter. In order to maintain a good fit to the observed \(r_{0}(L)\), one has to redistribute galaxies over haloes of different masses in order to counterbalance the changes in \(b_{h}(M)\) and \(\xi_{\text{lin}}(r)\). As long as these changes are not too large, one can always find a characteristic halo mass that has the right bias so that \(r_{0}(L)\) is consistent with the data. However, all these different models will predict different mass-to-light ratios \((M/L)_{M}\), simply because they require different halo occupation statistics. Therefore, any constraints on the average mass-to-light ratios of dark matter haloes, on any mass scale, will dramatically tighten the constraints on cosmological parameters.

One such constraint comes from galaxy clusters. Numerous studies, based on different techniques, have measured the mass-to-light ratios of clusters of galaxies (e.g. Carlberg et al. 1996; Bahcall et al. 2000; Lin et al. 2004; Popesso et al. 2005). As shown in BMY03, all these measurements are in good agreement with each other and suggest that \((M/L)_{CL} = (350 \pm 70) h (M/L)_{CL}\). Using this as a constraint on the CLF models puts tight constraints on the cosmological parameters. In fact, combining the CLF analysis with the first year WMAP results, BMY03 obtained that \(\Omega_{m} = 0.25_{-0.10}^{+0.07}\) and \(\sigma_{8} = 0.78 \pm 0.12\) (both 95 per cent CL), in excellent agreement with the 3-yr results from the WMAP mission (Spergel et al. 2006). The main problem with the WMAP1 cosmology is that it predicts mass-to-light ratios for clusters that are too large (see also Tinker et al. 2005; Vale & Ostriker 2006). The good agreement, both among these different studies and with the latest CMB constraints, demonstrates the strength and reliability of the CLF formalism (or equivalent techniques), especially when combined with constraints on mass-to-light ratios. It indicates that halo occupation modelling has matured to the point where it can be used to obtain tight and reliable constraints on cosmological parameters (see also Zheng & Weinberg 2005).

### 3.2 Faint-end slope of CLF

The lower left-hand panel of Fig. 4 shows that our CLF model predicts that the faint-end slope of the CLF, \(\alpha\), decreases with increasing halo mass. At around the cluster scale the models favour fairly steep faint-end slopes with \(\alpha \simeq -1.2 \pm 0.3\) (68 per cent CL), in good agreement with independent studies of the luminosity functions of individual clusters (e.g. Sandage, Bingelli & Tammann 1985; Beijersbergen et al. 2002; Trentham & Hodgkin 2002; Trentham & Tully 2002). Note, however, that since the CLF reflects the average luminosity function for haloes of a given mass, it is not necessarily a good description of the luminosity functions in individual systems. A more meaningful comparison is therefore with the CLFs that one can obtain directly from galaxy group catalogues by combining all groups in a relatively narrow mass bin.

The solid squares indicate the faint-end slope of the CLF thus obtained by Eke et al. (2004) from the 2PIGG group catalogue (see also Robotham et al. 2006), while the (red) solid dots correspond to the results obtained from our 2dFGRS group catalogue (see Yang et al. 2005b). Both results are in reasonable agreement with each other and with the confidence limits obtained from our CLF analysis (though the latter are not very strict). Note that our results only extend to \(M \lesssim 10^{14} h^{-1} M_{\odot}\); in order to obtain a sufficiently large number of massive groups, one needs to probe out to relatively high redshifts. However, because of the flux limit of the 2dFGRS we cannot probe the CLF of these groups to sufficiently low luminosities to be able to extract a reliable measure of the faint-end slope.

### 3.3 Satellite fractions

The satellite fraction as function of luminosity, \(f_{\text{sat}}(L)\), is an important quantity for a proper interpretation of galaxy–galaxy lensing measurements (Guzik & Seljak 2002; Mandelbaum et al. 2006;...
Yang et al. 2006) and for understanding PVDs (Slosar, Seljak & Tasitsiomi 2006; see also Section 5). Therefore, it is useful to check what our CLF models predict in terms of \( f_{\text{sat}}(L) \).

A satellite galaxy most likely resides in a more massive halo than a central galaxy of the same luminosity. Since halo bias depends on halo mass, the large-scale bias of galaxies of a given luminosity depends strongly on what fraction of them are satellites. Consequently, the observed clustering strength as function of luminosity can put strong constraints on \( f_{\text{sat}}(L) \). In the ‘deterministic’ case (see Section 2.4), the satellite fraction as function of luminosity is given by

\[
    f_{\text{sat}}(L) = \frac{1}{\Phi(L)} \int_{M_{\text{one}}}^{\infty} \Phi(L|M) n(M) \, dM
\]

with \( M_{\text{one}} \) defined according to \( L_{\text{one}}(M_{\text{one}}) = L \). In words, \( M_{\text{one}} \) is the mass scale at which one has exactly one galaxy brighter than \( L \), which is easily computed from equation (24) using a root finder. The lower right-hand panel of Fig. 4 shows the 68 and 95 per cent confidence levels on \( f_{\text{sat}}(L) \) computed from our CLF MCMC. The satellite fraction decreases with increasing luminosity, from \( 32 \pm 6 \) per cent at \( M_{\text{b}} - 5 \log h = -17 \) to \( 11 \pm 4 \) per cent at \( M_{\text{b}} - 5 \log h = -21 \) (both 68 per cent CL). In the WMAP1 cosmology, the satellite fractions are about \( +5 \) per cent higher, which is a small (but systematic) difference compared to the model uncertainties for a given cosmology.

For comparison, we overplot the results from three different studies. The dashed line shows the satellite fractions corresponding to the fiducial HOD model of Tinker et al. (2006b, hereafter TNWW). This model is constrained by the luminosity dependence of the clustering strength in the 2dFGRS. The two crosses indicate the satellite fractions inferred by Cooray (2006) from a CLF analysis of the Sloan Digital Sky Survey (hereafter SDSS), with vertical errorbars indicating the 68 per cent confidence levels. Finally, the solid circles and triangles with vertical errorbars (68 per cent CL) indicate the satellite fractions of early- and late-type galaxies, respectively, inferred by Mandelbaum et al. (2006) from a galaxy–galaxy lensing analysis of the SDSS.3 Remarkably, all these results are in good agreement with each other and with our CLF constraints.

3 For the results of Mandelbaum et al. (2006) and Cooray (2006), we have converted the SDSS \( r \)-band luminosities to the \( b_j \) band using the simplifying assumption that the luminosity ratio \( L/L^* \) is independent of the photometric band.
We therefore use the populated simulation box to construct a MGRS (as described in detail in Appendix B) to which we apply the group finder of YMBJ. The solid (red) histograms in Fig. 5 show the luminosity-gap statistic obtained from these mock group catalogues. Overall, the agreement between the mock and the data is remarkably good, indicating that our CLF model predicts realistic values of \( L_2/L_1 \). Somewhat unfortunately, the differences between the ‘deterministic’ and ‘random’ models are now much suppressed, so that it is no longer possible to clearly discriminate between these two models. Note that the mock group catalogue yields a distribution of \( \log[L_2/L_1] \) in the lowest halo mass bin which is very different from the true underlying distributions (dashed histograms), indicating that these low-mass haloes suffer quite substantially from interlopers, incompleteness effects and errors in halo mass. For the more massive haloes, however, the agreement between the true distributions and those obtained from the mock group catalogue is very satisfactory.

Systems with a relatively large luminosity gap, which most likely owes to the fact that the brightest galaxies in the halo have merged, are often termed as ‘fossil groups’ and have received a significant amount of attention in the recent literature (see Vikhlinin et al. 1999; Jones et al. 2003; D’Onghia et al. 2005; Milosavljević et al. 2006, and references therein). Following Jones et al. (2003) and Milosavljević et al. (2006), we define systems in which the second brightest galaxy is at least 2-mag fainter than the brightest galaxy (i.e. \( \log[L_2/L_1] \leq -0.8 \), indicated as dotted vertical lines in Fig. 5) as ‘fossil’ systems. With our 2dFGRS group catalogue, we are in a unique position to determine the fraction of fossil groups from a large and complete sample of optically selected galaxy groups. We obtain that the fraction of fossil systems increases with decreasing halo mass from 3.6 per cent for groups with \( 14 < \log[M/(h^{-1} M_\odot)] \leq 15 \) to 6.5 per cent for groups with \( 13 < \log[M/(h^{-1} M_\odot)] \leq 14 \) to 13.4 per cent for groups with \( 12 < \log[M/(h^{-1} M_\odot)] \leq 13 \) (in all three cases the Poissonian errors are less than 0.1 per cent). For comparison, Jones et al. (2003) obtained an incidence rate of 8–20 per cent for systems with an X-ray luminosity from diffuse, hot gas of \( \log[L_X, bol] \geq 2.5 \times 10^{41} h^{-2} \text{erg s}^{-1} \). Although this is relatively high compared to the fossil fractions in our 2dFGRS group catalogue, the latter have not been X-ray selected which complicates a straightforward comparison. In a recent paper, D’Onghia et al. (2005) used detailed hydrodynamical simulations to predict the fraction of haloes with \( M \sim 10^{14.5} h^{-1} M_\odot \) that have \( \log[L_2/L_1] \leq -0.8 \). From a total of 12 simulated groups, they obtain a fossil fraction of 33 \pm 16 per cent. Although consistent with ours at their 2\sigma level, the much lower fraction of fossil systems in our 2dFGRS group catalogue suggests a potential overmerging problem in their simulations.

As a final note of caution, we emphasize that the CLF predictions for the luminosity gap statistic are likely to be sensitive to the assumed Schechter form. If alternative functional forms yield luminosity gap statistics that are very different (after the construction of a mock group catalogue), the 2dFGRS data presented here may be useful to discriminate between different functional forms for the CLF.

4 HALO OCCUPATION STATISTICS

In this section, we describe the link between the CLF and the more often used HOD models. The latter aim at constraining the conditional probability distribution \( P(N \mid M) \) that a halo of mass \( M \) contains \( N \) galaxies. Here, and in what follows, whenever we talk about the occupation numbers \( N \), we mean the number of galaxies brighter than a given luminosity limit \( L_{\text{min}} \). Most studies to date have only focused on the first moment of \( P(N \mid M) \), which specifies the mean occupation numbers as function of halo mass. The same information can be extracted trivially from the CLF, for any \( L_{\text{min}} \), so that the relation between \( P(N \mid M) \) and \( \Phi(L \mid M) \) is given by

\[
\langle N \rangle_M = \int_{L_{\text{min}}}^{\infty} \Phi(L \mid M) \, dL.
\]

It is interesting to compare the shape of this \( \langle N \rangle_M \) predicted by the CLF, with the shape that is typically assumed in HOD models. Early HOD models often assumed that \( \langle N \rangle_M \) follows a simple power law (Jing, Mo & Börner 1998; Seljak 2000; Scoccimarro et al. 2001; Scannapieco 2002; Rozo, Dodelson & Frieman 2004; Collister & Lahav 2005) or a broken power law (Berlind & Weinberg 2002; Magliocchetti & Porciani 2003). More recently, it has become practice to adopt a somewhat more complicated form, motivated by a separate treatment of central and satellite galaxies, i.e. \( \langle N \rangle_M = \langle N_{\text{cen}} \rangle_M + \langle N_{\text{sat}} \rangle_M \) (e.g. Zehavi et al. 2001; Abazajian et al. 2005; Sefusatti & Scoccimarro 2005; Zheng et al. 2005; Tinker, Weinberg & Zheng 2006a). In all these models \( \langle N_{\text{sat}} \rangle_M \) is modelled as a power law (sometimes with a break at small \( M \)), while \( \langle N_{\text{cen}} \rangle_M \) is considered to change from zero at low \( M \) to unity at high \( M \), either via a simple step function at a characteristic mass, or via a somewhat broader transition function. These functional forms are largely motivated by the occupation statistics of dark matter subhaloes and of galaxies in numerical simulations and semi-analytical models (Kauffmann et al. 1999; Benson et al. 2000; Sheth & Diaferio 2001; Lahav 2005). Following the ‘deterministic’ method described in Section 2.4, the occupation statistics of central and satellite galaxies follow trivially from \( \langle N \rangle \); if \( \langle N \rangle \geq 1 \) then \( \langle N_{\text{cen}} \rangle = 1 \) and \( \langle N_{\text{sat}} \rangle = \langle N \rangle - 1 \). On the other hand, if \( \langle N \rangle < 1 \) then \( \langle N_{\text{cen}} \rangle = \langle N \rangle \) and \( \langle N_{\text{sat}} \rangle = 0 \).

With one additional assumption, one can in fact derive the full probability distribution \( P(N \mid M) \) from the CLF. Motivated by the fact that dark matter subhaloes reveal Poissonian statistics (Kravtsov et al. 2004), it has become standard to assume that the number of satellite galaxies follows a Poisson distribution. If we follow this assumption, which is also the standard procedure in HOD models, we have that

\[
P(N \mid M) = \begin{cases} P_1(N \mid M) & \text{if } M > M_{\text{one}} \\ P_2(N \mid M) & \text{otherwise}
\end{cases}
\]

Here \( M_{\text{one}} \) is defined in Section 3.3,

\[
P_1(N \mid M) = \begin{cases} 0 & \text{if } N = 0 \\ \langle N_{\text{sat}} \rangle^{N-1} \ exp\{\langle N_{\text{sat}} \rangle - \langle N_{\text{sat}} \rangle \} & \text{otherwise}
\end{cases}
\]

and

\[
P_2(N \mid M) = \begin{cases} 1 - \langle N_{\text{cen}} \rangle & \text{if } N = 0 \\ \langle N_{\text{cen}} \rangle & \text{if } N = 1 \\ 0 & \text{otherwise}
\end{cases}
\]

For completeness, it should be stated that this works both ways, and that in practice one can also compute the CLF from a given HOD model. Constraints on \( \langle N \rangle_M \) for a number of different \( L_{\text{min}} \) allows one to compute a CLF by simple differentiation (cf. Zehavi...
et al. 2005). However, the luminosity resolution of such a CLF is restricted by the number of different magnitude limits for which a HOD is constructed. For example, the HOD of Zehavi et al. (2005) consists of nine magnitude limits. For each of these, \( \langle N \rangle_M \) is fitted with three free parameters. In the end, this yields a CLF with a luminosity resolution of half a magnitude, which is described by a total of \( 9 \times 3 = 27 \) free parameters. For comparison, the CLF model used here as (only) eight free parameters and has infinite luminosity resolution.

4.1 Model predictions

The upper left-hand panel of Fig. 6 plots the average number of galaxies brighter than a given magnitude limit as function of halo mass. The magnitude limits are, from left to right, \( M_b - 5 \log h = -14, -15, \ldots, -21 \). Results are only shown for the best-fitting model from the WMAP3 MCMC, though the overall trends are qualitatively the same for all other models, including those for the WMAP1 cosmology. At bright magnitude limits, \( \langle N \rangle_M \) is close to a pure power law. At fainter magnitude limits, it starts to develop a low-mass shoulder, which, at the faintest magnitude limits, evolves into a separate peak. The results for \( M_b - 5 \log h \leq -18 \), however, are not very reliable, as there are no clustering constraints for these faint galaxies. The occupation numbers for these faint magnitude limits are merely ‘predictions’ that follow from our assumed functional form for the CLF.

The upper middle and upper right-hand panels of Fig. 6 plot the corresponding occupation statistics of central and satellite galaxies, respectively (see Section 2.4). The lower panels plot \( \langle N \rangle_M \), plus the contributions from central (dotted lines) and satellite (dashed lines) galaxies, for three magnitude limits, as indicated. Clearly, the functional forms of these occupation numbers are in qualitative agreement with the functional forms discussed above: \( \langle N_{\text{cen}} \rangle_M \) transits from zero at low \( M \) to unity at large \( M \), while \( \langle N_{\text{sat}} \rangle_M \) is well approximated by a power law at large \( M \) with an (exponential) truncation at low \( M \). However, a more detailed comparison shows that the \( \langle N \rangle_M \) of TNWW reveal more pronounced shoulders at \( \langle N \rangle_M = 1 \) with a sharper truncation at low \( M \). The sharpness of this zero-to-unity transition is a measure for the scatter in the conditional probability function \( P(\langle N \rangle_M \mid L_{\text{cen}}) \), which is the topic of discussion in Section 4.3.

Finally, in Fig. 7 we compare the halo occupation numbers predicted from our CLF MCMC with those obtained from our 2dFGRS group catalogue (cf. Table A1). Overall the agreement is satisfactory, especially for brighter magnitude limits. The group catalogue predicts a flattening of \( \langle N \rangle_M \) at \( \langle N \rangle_M \simeq 1 \), in disagreement with our CLF predictions. However, this is an artefact of the group finder: one can detect ‘groups’ with \( N = 1 \), but not those with \( N = 0 \) (cf. Yang et al. 2005b).

4.2 Power-law slopes

To make our predictions regarding the occupation numbers somewhat more quantitative, we use our WMAP3 MCMC to compute the slope of \( \langle N_{\text{sat}} \rangle_M \) at the high-mass end. Fig. 8 plots the 68 and 95 per cent confidence limits on \( \gamma \equiv d \log \langle N_{\text{sat}} \rangle_M / d \log M \) measured at \( \langle N_{\text{sat}} \rangle_M = 3 \) as function of the magnitude limit. This shows that there is a fairly large uncertainty on \( \gamma \), especially for faint magnitude limits. In addition, it shows that the value of \( \gamma \) does not depend strongly on the value of the magnitude limit used. The sudden dramatic increase of the confidence limits at \( M_b - 5 \log h = -20 \) owes to the fact that for some of the CLF models in the MCMC even the most massive haloes considered (\( M = 10^{16} h^{-1} M_\odot \)) have fewer than three satellites with \( M_b - 5 \log h \leq -20 \), so that \( \gamma \) is not defined.

The (red) solid dots correspond to the results obtained from our 2dFGRS group catalogue, also measured at \( N_{\text{sat}} = 3 \), and are in good agreement with the CLF constraints. The (green) horizontal
at the 1–2 (68 per cent CL). This value is consistent with our CLF predictions.

a numerical simulation. We have converted these number densities to (2004) for five different number densities of CDM haloes in a large of CDM subhaloes. These have been obtained by Kravtsov et al.

solid squares, which indicate the slopes of the occupation statistics from our 2dFGRS group catalogue. The same applies to the (black)

shown for three different magnitude limits, as indicated, and are compared to the results obtained from our 2dFGRS group catalogue (red, solid dots; see Table A1).

As mentioned above, the occupation statistics of TNWW seem to predict significantly sharper zero-to-unity transitions for \( \langle N_{\text{cen}} \rangle_M \), which implies significantly less scatter in \( P(M \mid L_{\text{cen}}) \). The width of this conditional probability distribution is interesting from the perspective of galaxy formation, as it contains information regarding the amount of stochasticity in galaxy formation. It is also important for a proper interpretation of galaxy–galaxy lensing measurements (Mandelbaum et al. 2005) and of the kinematics of satellite galaxies (van den Bosch et al. 2004).

We can use the CLF to compute the variance in log \( M \) of haloes that host a central galaxy of luminosity \( L_{\text{cen}} \). This is given by

\[
\sigma^2[\log M] = \frac{M_2}{M_0^2} - \left( \frac{M_1}{M_0} \right)^2
\]

(38)

with

\[
M_k = \int_0^\infty P(L_{\text{cen}} \mid M) [\log M]^k n(M) \, dM
\]

(39)

and with \( P(L_{\text{cen}} \mid M) \) given by equation (23). Here we have used that

\[
P(M \mid L_{\text{cen}})dM = \frac{P(L_{\text{cen}} \mid M)n(M)}{\int_0^\infty P(L_{\text{cen}} \mid M)n(M)dM} \, dM,
\]

(40)

which follows from Bayes’ theorem.

Fig. 9 plots the 68 and 95 per cent confidence limits on \( \sigma_{\log M}(L_{\text{cen}}) \) obtained from our WMAP3 MCMC using the ‘deterministic’ (upper panel) and ‘random’ (lower panel) \( P(L_{\text{cen}} \mid M) \). The CLF model predicts a pronounced increase of \( \sigma_{\log M} \) with increasing \( L_{\text{cen}} \). This is consistent with Fig. 6, which clearly shows that the zero-to-unity transition of \( \langle N_{\text{cen}} \rangle_M \) becomes less sharp for brighter magnitude limits. As expected, the scatter in \( P(M \mid L_{\text{cen}}) \) is higher in the ‘random’ case compared to the ‘deterministic’ case, especially at the faint end.

The dashed lines in Fig. 9 indicate \( \sigma_{\log M}(L_{\text{cen}}) \) for the B-band CLF from Cooray (2006) computed using (38). Although Cooray assumes a different functional form for the CLF, and uses a very different technique to constrain the CLF, the agreement with our results is remarkably good.

The (red) solid dots show the results obtained by TNWW from a HOD analysis of the 2dFGRS. TNWW assumed that \( P(M \mid L_{\text{cen}}) \) follows a lognormal distribution and used the projected correlation functions for different magnitude bins in an attempt to constrain the width of this distribution as a function of \( L_{\text{cen}} \). For \( L_{\text{cen}} < 10^{10} h^{-2} L_\odot \), however, the data could not meaningfully constrain the width of \( P(M \mid L_{\text{cen}}) \), and TNWW simply adopted a
constant value for the width of the lognormal distribution. The red dots in Fig. 9 show the $\sigma_{\log M}$ obtained by substituting the lognormal of TNWW in equations (38) and (39). Note that for $L_{\text{cen}} > 10^{10} h^{-2} M_{\odot}$, the resulting $\sigma_{\log M}$ increases strongly with increasing $L_{\text{cen}}$. Although in qualitative agreement with our results and those of Cooray (2006), the actual values for $\sigma_{\log M}$ are much smaller. Unfortunately, it is difficult to judge the significance of this difference, as TNWW do not give any uncertainties on their estimates.

Given the relevance of the amount of scatter in $P(M | L_{\text{cen}})$, for example, for weak lensing, it is important to try to obtain more direct constraints on $\sigma_{\log M}$. In More et al. (in preparation), we use satellite kinematics to show that $\sigma_{\log M}(L_{\text{cen}}) > 0.2$ for $L_{\text{cen}} > 3 \times 10^9 h^{-2} M_{\odot}$, which clearly rules out the relatively small scatter obtained (and assumed) by TNWW. It is unclear at present why these authors obtain a $\sigma_{\log M}(L_{\text{cen}})$ that is so much smaller. For example, as shown in Zehavi et al. (2005), one can change the sharpness of the zero-to-unity transition of $\langle N_{\text{cen}} \rangle_M$ and leave the fit to the galaxy–galaxy correlation function largely intact.

5 PAIRWISE VELOCITY DISPERSIONS

The peculiar velocities of galaxies are determined by the action of the gravitational field, and are therefore directly related to the matter distribution in the Universe. Consequently, the amplitude of galaxy peculiar velocities can yield useful, additional information regarding the universal relation between light and mass. One statistic that is particularly useful in this respect is the PVD, $\sigma_{12}(r)$, which is a measure of the relative peculiar velocity of a pair of galaxies as a function of their separation $r$. The PVDs can be obtained from the data as described in Section 5.1 below.

In Yang et al. (2004), we used detailed MGRSs (see Appendix B) constructed using our WMAP1 CLF in order to investigate what these CLF models predict for the PVDs of 2dFGRS galaxies. A comparison with the results of Hawkins et al. (2003) revealed that our MGRS based on the best-fitting CLF dramatically overpredicts the PVDs at scales of $\sim 1 h^{-1}$ Mpc by $\sim 350$ km s$^{-1}$. Since the PVD is extremely sensitive to the few richest systems in the sample (i.e. Mo, Jing & Börner 1993), one can lower the PVDs by lowering the occupation numbers of massive haloes. Within the uncertainties of the CLF parameters, we were able to find a model that could reproduce the observed PVDs. However, that model predicts an average mass-to-light ratio for clusters of $\sim 1000 h M_{\odot}/L_{\odot}$, which is much larger (by more than $7\sigma$) than the average mass-to-light ratio obtained from other, independent measurements (see Section 3.1).

Rather than lowering the average number of galaxies per cluster, one can also lower the PVDs by reducing the abundance of massive haloes. This, however, implies a change of cosmology. In Yang et al. (2004) we showed that a flat $\Lambda$CDM cosmology with $\Omega_m = 0.3$ and $\sigma_8 = 0.75$ could accurately reproduce the observed PVDs with a realistic mass-to-light ratio for clusters. In fact, we used this result to argue against the WMAP1 cosmology and in favour of a cosmology with a reduced $\sigma_8$ (see also van den Bosch et al. 2003b, 2005a and YMBJ).

The PVDs of Hawkins et al. (2003) were obtained from a large flux-limited sample. Although these already provide important constraints on the mass-to-light ratios of clusters (for a given cosmology), one can obtain even tighter constraints on the universal relation between light and mass by measuring the PVDs as a function of galaxy luminosity. Jing & Börner (2004, hereafter JB04) were the first to present a PVD analysis for galaxies in different luminosity intervals. Using the 2dFGRS, they found that the PVD at a scale of $k = 1 h$ Mpc$^{-1}$ has a minimum of $\sim 425$ km s$^{-1}$ for galaxies with $M_{b_J} - 5 \log h \sim -20.5$. Fainter galaxies, with magnitudes in the range $[-17, -19]$, were found to have much higher PVDs of $\sim 700$ km s$^{-1}$, almost as high as those of the brightest galaxies in the 2dFGRS (see red, solid triangles in Fig. 10). This indicates that a significant fraction of the fainter galaxies must be satellite galaxies in massive haloes.

A qualitatively similar result has been obtained by Li et al. (2006, hereafter L06) from an analysis of the SDSS. In their case, however, $\sigma_{12}(L)$ measured at $k = 1 h$ Mpc$^{-1}$ reveals a smaller dynamic range; the minimum occurs at $\sim 500$ km s$^{-1}$, while the PVDs for the fainter galaxies are $\lesssim 600$ km s$^{-1}$ (see blue, solid squares in Fig. 10).

Using one of the CLF models presented in Yang et al. (2003), JB04 constructed a mock 2dFGRS which they analysed in exactly the same way as the 2dFGRS data. Contrary to the data, the model PVDs were found to increases monotonically from $\sim 400$ km s$^{-1}$ at $M_{b_J} - 5 \log h = -17$ to $\sim 750$ km s$^{-1}$ at $M_{b_J} - 5 \log h = -21$. The CLF model thus severely underpredicts the PVDs of faint galaxies, and does not reveal the pronounced minimum near $M_{b_J} - 5 \log h \sim -20.5$. However, there is a considerable amount of freedom in the
of the 2dFGRS) whose magnitude and redshift limits are indicated in Table 3.

Let \( r_0 \) and \( r_e \) be the pair separations perpendicular and parallel to the line of sight, respectively. For each of our volume-limited samples, we compute the 2PCF \( \xi(r_0, r_e) \), using the estimator introduced by Hamilton (1993). Random samples are constructed from our MGRSs (see Appendix B) by randomizing the coordinates of all mock galaxies. We use this two-dimensional 2PCF to compute the PVD from the galaxy power spectrum in redshift space, \( P^{\text{obs}}(k, \mu) \), which is approximately related to the power spectrum in real space, \( P(k) \) according to

\[
P^{\text{obs}}(k, \mu) = P(k)(1 + \beta \mu^2 + D[k \mu \sigma_1(k)] (1)
\]

(Peacock & Dodds 1994, Cole, Fisher & Weinberg 1995) with \( k \) being the wavenumber and \( \mu \) being the cosine of the angle between the wavevector and the line of sight. The factor \( (1 + \beta \mu^2) \) accounts for the compression due to infall, with \( \beta \) being the linear redshift-distortion parameter, while \( D[k \mu \sigma_1(k)] \) is the damping function

---

**Notes.** Column (1) specifies the absolute magnitude limit for each volume-limited sample, while the median magnitude is listed in Column (2). The minimum and maximum redshifts of each sample are listed in Columns (3) and (4), respectively, and the total number of 2dFGRS galaxies in each sample is listed in Column (5). Note that only galaxies with a redshift completeness greater than 0.7 are selected. Finally, Column (6) lists the PVDs in the 2dFGRS measured at \( k = 1 \text{ h Mpc}^{-1} \), plus the (cosmic variance) error determined from eight MGRSs.
that accounts for the random motion of galaxies within dark matter haloes. We follow JB04 and L06 and assume that this damping function has a Lorentz form

$$D(k, \mu, \sigma_1(k)) = \left[ 1 + \frac{1}{2} k^2 \mu^2 \sigma_1^2(k) \right]^{-1},$$

(42)

and compute the redshift space power spectrum for each volume-limited sample in Table 3 by Fourier transforming the corresponding 2PCF:

$$P^{\mu\pi}(k, \mu, \sigma_1(k)) = 2\pi \int dr_x \int dr_y r_x \xi(r_x, r_y) \cos(k_2 r_y)$$

$$\times J_0(k r_y) W(r_y, r_x)$$

(43)

(JB04). Here $J_0$ is the zeroth-order Bessel function, $k_2$ and $k_3$ are the wavenumbers perpendicular and parallel to the line of sight, and

$$W(r_y, r_x) = \exp \left( -\frac{r_x^2 + r_y^2}{2 S^2} \right)$$

(44)

is a Gaussian smoothing function (with smoothing scale $S = 20 h^{-1}$ Mpc) which is used to suppress the impact of fluctuations in $\xi(r_x, r_y)$ at large separations (see JB04 for details). We compute $\xi(r_x, r_y)$ in equal logarithmic bins of $r_y$ ($\Delta \ln r_y = 0.23$) and in equal linear bins of $r_x$ ($\Delta r_x = 1.0 h^{-1}$ Mpc). The $r_x$ integral in equation (43) is performed over the interval $-50 \leq r_x \leq 50 h^{-1}$ Mpc, while we integrate $r_y$ from 0.1 to $50 h^{-1}$ Mpc.

Finally, we determine the real-space power spectrum $P(k)$ and the PVDs $\sigma_1(k)$ by modelling the measured $P^{\mu\pi}(k, \mu, \sigma_1(k))$ using equation (41) with $\beta = 0.45$. Detailed tests in JB04 and L06 have shown that keeping $\beta$ fixed at this value yields reliable results. The best-fitting values for $\sigma_1(k)$ ($k = 1 h$ Mpc$^{-1}$) thus obtained are listed in Table 3 and are shown in Fig. 10 as black, open circles. The errorbars are obtained from eight WMAP1 mock redshift surveys (see Yang et al. 2004 for details) and indicate the expected scatter due to cosmic variance. We have simply assumed that the cosmic variance for the WMAP1 cosmology is the same as that for the WMAP1 cosmology. Although obviously a crude assumption, our ‘cosmic variance errors’ are significantly larger than those of L06, which have been obtained using bootstrapping. We therefore believe that our errors are sufficiently conservative.

Comparison of these results with those of JB04 and L06, reveals good mutual agreement at $M_h = -5 \log h \gtrsim -19$. For fainter galaxies, however, our analysis yields PVDs that are $\sim 150$ km s$^{-1}$ lower than those of JB04, with the results of L06, which are based on the SDSS, roughly in between. Since our analysis is identical to that of JB04, these differences reflect the slightly different selection criteria. Whereas JB04 used flux-limited samples with $0.02 \lesssim z \lesssim 0.25$, we use volume-limited samples with the restrictions that $0.01 \lesssim z \lesssim 0.20$. Another potential source of this difference is the relative sensitivity to the exact scale at which the PVDs are measured. As can be seen from Fig. 7 in JB04, their $\sigma_1(k)$ for galaxies with $-18.5 < M_h < -17.5$ reveals a pronounced, sharp peak of $\sim 725$ km s$^{-1}$ at $k = 1 h$ Mpc$^{-1}$. However, at slightly higher or lower $k$, the PVDs are $\sim 550$ km s$^{-1}$ in much better agreement with our results and those of L06.

5.2 Comparison with CLF models

In order to predict PVDs from our CLF, we construct detailed MGRSs using the CLF and cosmological N-body simulations (dark matter only). These MGRSs are constructed to be directly comparable to the 2dFGRS, as described in detail in Appendix B. We analyse these MGRSs using exactly the same procedure (described above) as used for the 2dFGRS data, so that the model-data comparison is as fair as possible.

The solid (red) line in the right-hand panel of Fig. 10 indicates the PVDs obtained from the MGRS constructed from the best-fitting CLF (called WMAP1 in Table 2). For $M_h = -5 \log h \lesssim -19.5$, this model predicts PVDs that are in reasonable agreement with the data. For fainter samples, however, the PVDs are clearly too low compared to the 2dFGRS. This is in qualitative agreement with JB04, even though our analysis is for the WMAP3 cosmology, while that of JB04 was for a WMAP1 cosmology.

In order to probe the uncertainties on $\sigma_1$ due to the uncertainties on the CLF parameters, ideally one would construct a MGRS for each of the 2000 models in our MCMC. Unfortunately, the construction of MGRSs and their subsequent analysis is computationally too expensive rendering this impractical. Instead, we proceed as follows. Since the mass-to-light ratio of clusters and the satellite fractions are the two model aspects that most strongly impact on $\sigma_1$, we have searched the MCMC for two models that more or less bracket the 95 per cent confidence limits of our CLF model. The parameters of these models, called WMAP3b and WMAP3c, are listed in Table 2, while Fig. 11 shows the mass-to-light ratios and satellite fractions of these models.

The dashed (blue) and dotted (green) lines in Fig. 10 show the PVDs of models WMAP3b and WMAP3c, respectively. Model WMAP3b predicts significantly higher satellite fractions and lower cluster mass-to-light ratios than the best-fitting model (WMAP3a). Consequently, the PVDs for faint galaxies are much larger, bringing in much better agreement with the PVDs obtained from the 2dFGRS. In order to quantitatively compare between different models, we compute the formal $\chi^2$ using the ‘cosmic variance’ errorbars obtained from our eight mock redshift surveys. This yields $\chi^2$ values of 95.7 and 89.4 for models WMAP3a and WMAP3b, respectively. Despite the clear improvement at the faint end, the goodness-of-fit of model WMAP3b is only marginally better than that for model WMAP3a. This owes almost entirely to the fact that model WMAP3b severely overpredicts the PVD for galaxies with $M_h < -5 \log h \simeq -20.4$: this single data point contributes 80.9 to the total $\chi^2$.

As expected, model WMAP3c predicts PVDs that are even lower than those in the case of model WMAP3a, in clear disagreement with the data ($\chi^2 = 147.4$). It does, however, accurately match the PVD at $M_h = -5 \log h \simeq -20.4$. This suggests that perhaps a model with a high $f_{\text{sat}}$ at the faint end, and a low $f_{\text{sat}}$ at the high end, could fit the PVDs at all luminosities. Model WMAP3d, which we extracted from our MCMC, meets these criteria (see Fig. 11), and indeed yields PVDs that are in reasonable agreement with the data ($\chi^2 = 31.8$). It does dramatically underpredict the PVDs at the bright end, but since the corresponding (cosmic variance) errors are huge, the contribution to the total $\chi^2$ is only modest.

Thus we conclude that, within the WMAP3 cosmology, one can find halo occupation models that can provide a reasonable, simultaneous fit to the luminosity dependence of the clustering strength and the luminosity dependence of the PVDs. However, this does come at a price. The best-fitting model (WMAP3d) is an extreme model within the MCMC; this is evident from both Table 2 and Fig. 11, which show that model WMAP3d has model parameters, mass-to-light ratios and satellite fractions that differ substantially from the best-fitting model. Furthermore, this model still does not fit the PVDs completely satisfactorily. In particular, it does not reveal a pronounced minimum in $\sigma_1(L)$, as observed. In fact, we have tested a number of additional models from our MCMC with similar $f_{\text{sat}}(L)$ as model WMAP3d, but none fair any better in this
respects. We have also tested models with a ‘random’, rather than a ‘deterministic’ sampling of \( L_{\text{con}} \), but this does not have a significant impact on the PVDs. TNWW showed that their HOD model was able to reproduce the observed shape of \( \sigma_{12}(L) \), but since they adopted a WMAP1 cosmology, their PVDs were systematically too high by \( \sim 150 \, \text{km s}^{-1} \). Although we only tested a hand full of models (selected in a strongly biased way), we therefore conclude that the detailed luminosity dependence of the PVDs remains a challenge for the halo occupation models. In the next section, we discuss possible implications of these findings.

6 CONCLUSIONS

Using the CLF formalism and data from the 2dFGRS, we have constrained the universal relation between light and mass. Using a MCMC we probe the complete parameter space of our models, and provide confidence limits on all derived quantities. With respect to our previous CLF studies, we have made the following changes and improvements.

(i) We have adopted a flat \( \Lambda \)CDM cosmology with parameters advocated by the 3-yr data release from the WMAP mission.

(ii) We have modelled the 2dFGRs data on its light cone.

(iii) We have taken the scale dependence of the halo bias into account.

(iv) We no longer impose that the mass-to-light ratios of haloes with \( M \geq 10^{14} \, h^{-1} \, M_{\odot} \) are constant.

The change in cosmology (lower \( \Omega_{\text{m}} \), lower \( \sigma_8 \) and lower spectral index) causes a reduction in the mass-to-light ratios of dark matter haloes ranging from \( \sim 25 \) to \( \sim 45 \) per cent, depending on the mass scale. As anticipated, this removes an important problem with previous CLF and HOD models which had a tendency to predict mass-to-light ratios for clusters that were too high (van den Bosch et al. 2003b,c; Yang et al. 2004; Tinker et al. 2005; Vale & Ostriker 2006).

Taking account of the light-cone modelling and the scale dependence of the halo bias only has a mild impact on our results, improving the accuracy of our models by \( \sim 5\)–\(10 \) per cent. We emphasize, though, that the impact of these effects can be much larger when using data out to higher redshift, or when using clustering data on smaller scales, compared to what we have used here.

We have compared various predictions of our CLF model with results obtained from our 2dFGRS group catalogue. We found excellent agreement for the average mass-to-light ratios, the luminosities of central galaxies as function of halo mass, the faint-end slope of the CLF, the occupation numbers in various luminosity bins, and the luminosity-gap statistic. The fact that these two completely different methods yield results in such good agreement, and for such a wide variety of statistics, is a major success for both the CLF formalism and the halo-based group finder of YMBJ. The CLF model also predicts that the satellite fraction decreases with increasing luminosity, in excellent agreement with the HOD analyses of TNWW and Cooray (2006), as well as with the constraints obtained by Mandelbaum et al. (2006) from a galaxy–galaxy lensing analysis of the SDSS.

One outstanding issue regarding the mass-to-light ratios regards the actual slope of \( \langle M/L \rangle_{3d} \) at the massive end \( (M \gtrsim 10^{14} \, h^{-1} \, M_{\odot}) \). While the group catalogue of YMBJ yields mass-to-light ratios that continue to increase roughly as \( (M/L)_{3d} \propto M' \) with \( \gamma = 0.33 \pm 0.05 \), an alternative group catalogue by Eke et al. (2004), also based on the 2dFGRS, predicts that \( \gamma \to 0 \) at the massive end. Unfortunately, the clustering data used to constrain the CLF cannot discriminate between these different values for \( \gamma \). Although recent, independent studies seem to favor somewhat intermediate values of \( \gamma = 0.2 \pm 0.08 \) (e.g. Popesso et al. 2005), the fact that two group catalogues constructed from the same data set yield such wildly different results, accentuates the need for more thorough investigations.

We also presented a detailed description of the link between the CLF and the more often used HOD models. In particular, we have shown how to compute the full halo-occupation distribution, \( P(\, | \, M) \), from the CLF for any range in luminosities. In addition, we have compared the shape of \( \langle N \rangle_{3d} \) predicted by our CLF models with that typically assumed in HOD models. Although they agree qualitatively, the HOD models typically adopt a zero-to-unity transition for \( \langle N \rangle_{3d} \) which is much sharper than what we predict with our CLF. This implies that the CLF predicts probability distributions \( P(\, | \, L_{\text{con}}) \) that are much broader than what is typically assumed in HOD models. The amount of scatter in \( P(\, | \, L_{\text{con}}) \) plays an important role in the interpretation of weak lensing measurements and
of satellite kinematics. In More et al. (in preparation), we present a
strict lower limit on $\sigma_{\log M}$, obtained from satellite kinematics, which
rules out values for $\sigma_{\log M}$ lower than $\sim 0.2$.

Finally, we have studied the luminosity dependence of the PVDs,
$\sigma_{12}$, of 2dFGRS galaxies. Using ten volume-limited samples, we
obtain that $\sigma_{12}(L)$ reveals a local minimum at $M_b = 5 \log h \simeq -20.4$,
in good qualitative agreement with JB04 and L06. At the faint end, however,
we obtain PVDs that are $\sim 150$ km s$^{-1}$ lower than those of
JB04. Since we used exactly the same analysis technique as JB04,
these differences must reflect the different selection criteria. Using
detailed MGRSs, we compared these $\sigma_{12}(L)$ with predictions from
our CLF models. In agreement with previous studies (e.g. Mo et al.
1993; Slosar et al. 2006; Tinker 2007), we find that the PVDs are
extremely tight, thus offering great potential to constrain both
mass-to-light ratios. This is good news since the clustering data
used to constrain the CLF leave relatively large uncertainties
regarding these quantities. Simultaneously matching $r_0(L)$ and $\sigma_{12}(L)$
therefore allows us to strongly tighten the constraints on parameter
space. In particular, for the WMAP3 cosmology used here, we find
that $\sigma_{12}(L)$ requires models with relatively low mass-to-light ratios
for clusters $\langle M/L \rangle_{12} \simeq 215 h (M/L)_{12}$ and with a satellite fraction that decreases from $\sim 45$ per cent at $M_b = 5 \log h \simeq -18.5$ to
$\sim 10$ per cent at $M_b = 5 \log h \simeq -20.5$.

In terms of the likelihood distributions obtained from our MCMC,
these values are typically $\gtrsim 2\sigma$ away from the median, indicating that
our CLF model is not capable of accurately fitting $r_0(L)$ and $\sigma_{12}(L)$
simultaneously. In particular, we were unable to find a CLF model in our
MCMC that could reproduce the pronounced minimum in $\sigma_{12}(L)$ at
$M_b = 5 \log h \simeq -20.4$. This suggests either (i) that we are dealing with the wrong cosmology, or (ii) that the CLF parametrization used here is not sufficiently general. Although we certainly cannot rule out this latter option, we believe that option (i) is the more likely cause for this outstanding problem. This is motivated by some of our previous results. In Yang et al. (2004) we used our CLF formalism and the PVDs measured by Hawkins et al. (2003) to argue against the WMAP1 cosmology and in favour of a cosmology with $\Omega_m \simeq 0.3$ and $\sigma_8 \simeq 0.75$. The WMAP3 cosmology adopted here has $\Omega_m = 0.238$ and $\sigma_8 = 0.744$. Lowering $\Omega_m$ and/or $\sigma_8$ reduces the abundance of massive haloes, which in turn implies that lower cluster mass-to-light ratios are needed in order to explain the observed PVDs. The fact that the WMAP3 cosmology studied here requires relatively low values for $\langle M/L \rangle_{12}$, while our WMAP1 studies required relatively high cluster mass-to-light ratios, therefore suggests a cosmology with values for $\Omega_m$ and/or $\sigma_8$ intermediate between those of the WMAP1 and WMAP3 cosmologies. We leave it for future studies to see whether indeed such a cosmology can yield a CLF that can simultaneously match the $r_0(L)$ and $\sigma_{12}(L)$ with realistic model parameters. As a final note, however, we wish to emphasize that the combined constraints from $r_0(L)$ and $\sigma_{12}(L)$ are extremely tight, thus offering great potential to constrain both cosmological parameters and halo occupation statistics. The CLF formalism presented here is ideally suited for such a task.

ACKNOWLEDGMENTS

We thank the referee, Jeremy Tinker, for his detailed and insight-
ful comments that greatly helped to improve the paper. FCvdB ac-
knowledge useful discussions with Andreas Berlind, Aaron Dutt-
on and Andrey Kravtsov. The simulations used in this paper have
been carried out on the zBox2 supercomputer (http://www-
theorie.physik.unizh.ch/~dotter/zbox2/) at the Institute for Theo-
retical Physics in Zurich, Switzerland.

are brighter than the flux limit of the survey, we correct for missing members using an empirical self-calibration based on the more massive haloes having the same number density. Note that this method has been tested in great detail against MGRS (YMBJ; Yang et al. 2003a). This group finder is optimized to find groups to which galaxies belong, rather than just the more massive haloes that contain them.

Van den Bosch et al. (2007) have shown that the Halo occupation statistics (HOS) for the more massive haloes have the same number density. Note that this method has been tested in great detail against MGRS (YMBJ; Yang et al. 2003a). This group finder is optimized to find groups to which galaxies belong, rather than just the more massive haloes that contain them.

Throughout this paper, we compare various CLF predictions with results obtained from our 2dFGRS group catalogue. The construction of this catalogue is based on a halo-based group finder, which is described in YMBJ. This group finder is optimized to group together galaxies that reside in the same dark matter halo, and has been tested in great detail against MGRSs (YMBJ; Yang et al. 2005b; Weinmann et al. 2006a,b).

Contrary to most other studies, we do not determine the group masses from the velocity dispersion of the group members. Instead, we estimate the group masses from the group luminosity $L_{18}$, defined as the total luminosity of all group members brighter than $M_{b} = 5 \log h = -18$. Detailed tests have shown that this method is significantly more accurate than using the velocity dispersion of group members (see appendix B of Weinmann et al. 2006a). For distant groups, in which not all galaxies above this magnitude limit are brighter than the flux limit of the survey, we correct for missing members using an empirical self-calibration based on the groups that are significantly closer. We use this group finder to find groups to which galaxies belong, rather than just the more massive haloes that contain them.

To convert from $L_{18}$ to a halo mass $M$, we make the assumption that there is a one-to-one relation between $L_{18}$ and $M$. For each group we determine the number density of all groups brighter (in terms of $L_{18}$) than the group in consideration, and we then use the halo mass function for the WMAP3 cosmology to find the value of $M$ for which the more massive haloes have the same number density. Note that 

APPENDIX A: THE 2dFGRS GROUP CATALOGUE

Throughout this paper, we compare various CLF predictions with results obtained from our 2dFGRS group catalogue. The construction of this catalogue is based on a halo-based group finder, which is described in YMBJ. This group finder is optimized to group together galaxies that reside in the same dark matter halo, and has been tested in great detail against MGRSs (YMBJ; Yang et al. 2005b; Weinmann et al. 2006a,b).

Contrary to most other studies, we do not determine the group masses from the velocity dispersion of the group members. Instead, we estimate the group masses from the group luminosity $L_{18}$, defined as the total luminosity of all group members brighter than $M_{b} = 5 \log h = -18$. Detailed tests have shown that this method is significantly more accurate than using the velocity dispersion of group members (see appendix B of Weinmann et al. 2006a). For distant groups, in which not all galaxies above this magnitude limit are brighter than the flux limit of the survey, we correct $L_{18}$ for the missing members using an empirical self-calibration based on the groups that are significantly closer. We use this group finder to find groups to which galaxies belong, rather than just the more massive haloes that contain them.

To convert from $L_{18}$ to a halo mass $M$, we make the assumption that there is a one-to-one relation between $L_{18}$ and $M$. For each group we determine the number density of all groups brighter (in terms of $L_{18}$) than the group in consideration, and we then use the halo mass function for the WMAP3 cosmology to find the value of $M$ for which the more massive haloes have the same number density. Note that
two large N-body simulations of $N=512^3$ dark matter particles each. These simulations have been carried with PDKGRAV, a tree code written by Joachim Stadel and Thomas Quinn (Stadel 2001). Each simulation evolves the distribution of the dark matter in the WMAP $Λ$CDM cosmology ($Ω_m=0.238$, $Ω_Λ=0.762$, $Ω_b=0.042$, $h=0.73$, $σ_8=0.75$, $n_s=0.951$). The initial conditions are generated with the GRAFIC2 package (Bertschinger 2001), which also computes the transfer function as described in Ma & Bertschinger (1995). The two simulations have periodic boundary conditions and box sizes of 100 and 300 $h^{-1}$ Mpc, respectively. The particle masses are $4.92 \times 10^6$ and $1.33 \times 10^{10} h^{-1} M_☉$ for the small and large box simulations, respectively. In what follows we refer to the simulations with $L_{box}=100$ and $300 h^{-1}$ Mpc as $L_{100}$ and $L_{300}$, respectively.

We follow Yang et al. (2004) and replicate the $L_{300}$ box on a $4 \times 4 \times 4$ grid. The central $2 \times 2 \times 2$ boxes, are replaced by a stack of $6 \times 6 \times 6 L_{100}$ boxes, and the virtual observer is placed at the centre (see fig. 11 in Yang et al. 2004). This stacking geometry circumvents incompleteness problems in the mock survey due to insufficient mass resolution of the $L_{100}$ simulations, and allows us to reach the desired depth of $z_{max}=0.20$ in all directions.

Dark matter haloes are identified using the standard FOF (friends-of-friends) algorithm with a linking length of 0.2 times the mean interparticle separation. Unbound haloes and haloes with less than 10 particles are removed from the sample. The resulting halo mass functions are in excellent agreement with the analytical halo mass function of Sheth et al. (2001). We populate the dark matter haloes with galaxies of different luminosity using our CLF. Because of the mass resolution of the simulations and because of the completeness limit of the 2dFGRS, we adopt a minimum galaxy luminosity of $L_{min}=10^7 h^{-2} L_☉$. The halo occupation statistics of these galaxies follow from the CLF as described in Section 4. Luminosities are drawn using either the ‘deterministic’ or the ‘random’ sampling method described in Section 2.4, whereby we always assume that the central galaxy is the brightest galaxy in its halo.

The positions and velocities of the galaxies with respect to the halo centre of mass are drawn assuming that the brightest galaxy in each halo resides at rest at the centre. The satellite galaxies follow a number density distribution that is identical to that of the dark matter particles, and are assumed to be in isotropic equilibrium within the dark matter potential. To construct MGRSs, we use the same selection criteria and observational biases as in the 2dFGRS, making detailed use of the survey masks provided by the 2dFGRS team (Colless et al. 2001; Norberg et al. 2002). We also mimic fibre collisions and image blending as described in detail in van den Bosch & Okamoto (2005c). The final MGRSs accurately match the clustering properties, the apparent magnitude distribution and the redshift distribution of the 2dFGRS, and mimic all the various incompleteness effects, allowing for a direct, one-to-one comparison with the true 2dFGRS.
