ABSTRACT

We show that the collapsar model of gamma-ray bursts results in a series of successive shocks and rarefaction waves propagating in the “cork” of stellar material being pushed ahead of the jet, as it emerges from the massive stellar progenitor. Our results are derived from analytical calculations assuming a hot, ultrarelativistic 1-D flow with an initial Lorentz factor $\Gamma_j \sim 100$. The shocks result in a series of characteristic, increasingly shorter and harder thermal X-ray pulses, as well as a non-thermal $\gamma$-ray pulse, which precede the usual non-thermal MeV $\gamma$-rays. We consider jets escaping from both compact (CO or He dwarf) and blue supergiant stellar progenitors. The period, fluence and hardness of the pulses serves as a diagnostic for the size and density of the outer envelope of the progenitor star.

Subject headings: Gamma-rays: bursts – X-rays: bursts – Cosmology: miscellaneous – Stars: supernovae: general

1. Introduction

The non-thermal radiation from shocks in a relativistic fireball jet after emerging from a collapsing massive stellar system (collapsar) is the leading theoretical explanation for the family of “long” gamma-ray bursts (GRB) with $\gamma$-ray durations longer than about $t_b \sim 10$ s (Woosley 1993, Paczyński 1998; see Mészáros 2002 for a review). The jet is thought to arise from a brief accretion episode of a rotating debris torus around a central black hole formed as the stellar core collapses. The nature and history of the massive star, however, is so far largely a matter of hypothesis and calculation, and alternative stellar progenitor systems are conceivable, both for the long and especially for the shorter bursts.

The duration of the TeV neutrino burst expected from shocks in the jet before it emerges is a possible diagnostic for the pre-emergence jet history and for the dimensions or column density
of the progenitor stellar system (Mészáros & Waxman 2001). Previous analytical work on shock and jet emergence has been done by Matzner & McKee 1999, Mészáros & Rees 2001, Matzner 2002, and numerical calculations of relativistic jets have been done by Marti, Müller, Font, Ibañez & Marquina, 1997; Aloy, Müller, Ibañez, Marti & MacFadyen, 2000; and Zhang, Woosley & McFadyen, 2002. Here we concentrate on possible photon signatures of the jet as it emerges, which precedes the usual gamma-ray emission and the subsequent longer wavelength afterglow. This has been considered by Ramirez-Ruiz, McFadyen & Lazzati (2001), who infer an X-ray precursor to the burst from the portion of the stellar envelope shocked by the jet. Here we investigate in some detail, using analytical 1-D methods in the ultrarelativistic limit, the jet emergence process and the shock heating and expansion of the plug of stellar material propelled by it, resembling an ejected cork.

In the initial stage of ejection the cork is optically very thick to scattering, and it experiences successive shocks and rarefactions as the optical depth decreases during its overall expansion. This leads to an X-ray photon precursor to the usual GRB emission, consisting of a pattern with an initial rise and decay followed by a brighter and harder peak, possibly repeated a few times with decreasing period. The characteristic timescale of the initial decay and the ratio of its amplitude to that of the peak differ substantially depending on the density and extent of the envelope, thus providing a potential diagnostic for the pre-burst stellar configuration. These precursor patterns should be detectable with instruments to be flown in the next few years.

2. Jet propagation

We assume a jet with isotropic equivalent luminosity \( L_{\text{iso}} \gtrsim 10^{52} L_{52} \text{ erg s}^{-1} \) and Lorentz factor \( \Gamma_j \sim 10^2 \). As the jet advances through the star, it drives forward a bow shock into the star. The jet is capped by a "cork" composed of a termination shock advancing into the star, and a reverse shock moving back into the jet, where the tenuous and highly relativistic jet gas is suddenly decelerated and compressed. Both the shocked jet plasma and the shocked stellar plasma advance inside the star with a jet head Lorentz factor \( \Gamma_h \ll \Gamma_j \), corresponding to a velocity \( \beta_h \). Figure shows a schematic description of the multiple shock structure. In the rest frame of the shocked, decelerated plasma, the fast jet moves with a Lorentz factor \( \sim \Gamma_j / 2 \Gamma_h \). During propagation in the He core, the high density ahead of the jet, \( \rho \sim 1 \text{ g cm}^{-3} \), implies deceleration of the jet plasma to a sub-relativistic velocity. However, beyond the C/O or He core edge at \( r \gtrsim 10^{10} - 10^{11} \text{ cm} \), there is a sharp drop in the density, e.g. the density of an H envelope, if present, is typically \( \rho \sim 10^{-5} - 10^{-7} \text{ g cm}^{-3} \), and the jet can accelerate to relativistic velocity. We have used Matzner & McKee's parametrization of the density drop near the edge of the star, \( r = R_* \),

\[
\rho = \rho_0 \left( \frac{R_*}{r} - 1 \right)^n ,
\]

where \( n = 3 \,(3/2) \) for radiative (convective) envelope. Eq. (1) holds for a polytropic plasma at radii beyond which the envelope contribution to the gravitational potential is small. We consider
three progenitor examples: i) the edge of the C/O progenitor model of SN1998bw (Woosley, Eastman & Schmidt 1999), approximately described by \( \rho \approx 5 \times 10^2 g/cm^3 \), \( R_* = 10^{10} \) cm and \( n = 3 \); ii) the outer part of the He mantle of the pre-supernova model, evolved by Woosley, Langer & Weaver (1993) from a 35\( M_\odot \) main sequence star, approximately described by Eq. (1) with \( \rho_* = 2 g/cm^3 \), \( R_* = 10^{11} \) cm and \( n = 3 \); and iii) the envelope of the blue supergiant (BSG) CO core is of order \( t \approx 10^3 \) s.

The pressure behind the forward shock is given, for \( \Gamma_h \gg 1 \), by \( P_h = (4/3) \Gamma_h^2 \rho c^2 \), and for \( \beta_h \ll 1 \), by \( P_h = [(\gamma + 1)/2] \rho \beta_h^2 c^2 \), where \( \gamma = 4/3 \) is the adiabatic index of the plasma (radiation dominated). Equating \( P_h \) with the pressure behind the reverse shock, \( P_r = (4/3)(\Gamma_j/2 \Gamma_h)^2 n_j m_p c^2 \), for \( \Gamma_h \gg 1 \) and \( P_r = (4/3) \Gamma_j^2 n_j m_p c^2 \) for \( \beta_h \ll 1 \), where the jet proper proton density \( n_j = L_{iso}/(4\pi r^2 \Gamma_j^2 m_p c^2) \). (For a discussion of relativistic flows and shock jump conditions, see e.g., Begelman, Blandford & Rees 1984). The extreme relativistic limit gives (Mészáros & Waxman 2001)

\[
\Gamma_h \sim \begin{cases} 
1.6 L_{iso}^{1/4}/r_1^{1/2} \rho_{-3}^{1/4} & \text{H;} \\
0.9 L_{iso}^{1/4}/r_{11}^{1/2} \rho_{-3}^{1/4} & \text{He}
\end{cases}
\]

for the H-envelope of a BSG (H) or a He star, while the non-relativistic limit gives

\[
\beta_h \sim \begin{cases} 
1.6 L_{iso}^{1/2}/r_{11} \rho_{-3}^{1/2} & \text{He;} \\
0.6 L_{iso}^{1/2}/r_{10} \rho_{-3}^{1/2} & \text{CO}
\end{cases}
\]

for the He or CO cores, where more exactly \( \beta_h \leq 1 \) and \( \Gamma_h \geq 1 \) would hold; \( L_{iso} = 10^{52} L_{52} \text{erg s}^{-1} \) is the jet isotropic equivalent luminosity, \( r = 10^2 r_x \) is the shock radius, and \( \rho = 10^2 \rho_x g \text{ cm}^{-3} \) is the corresponding density at that radius. These values are for the main part of the cork, including the shocked jet and the bulk of the shocked stellar material. Thus, for \( r \sim 0.9 R_* \) in all cases the jet head velocity is at least marginally relativistic, and this approximation gets better as \( r \to R_* \). This implies that, even though the jet injected at the base of the jet is assumed to be ultrarelativistic, \( \Gamma_j = 10^2 \Gamma_2 \gg 1 \), the jet head advances sub-relativistically for most of its initial crossing of the stellar interior. This is due to the initial inertia of the dense stellar material which needs to be pushed ahead and aside (e.g., Mészáros & Rees, 200 for an analytical discussion). A similar relativistic injection and subrelativistic jet head advance occurs in AGN jets encountering the intergalactic medium, e.g., Begelman et al.1984. The jet crossing time out to the He (or CO) core edge is of order \( t_{core} \sim 30 r_{11} \) s for a jet which has reached \( v_h \sim c \) near the core edge, suggesting that compact \( r \lesssim 10^{11} \) cm stars such as He stars or pre-WR stars are likely GRB progenitors (see also MacFadyen et al. 2001 and Matzner 2002).

However, if there is an H-envelope beyond the C/O/He core, where the density drops steeply by \( 10^{-5} - 10^{-7} \), momentum conservation indicates that \( \Gamma_h \) for the entire cork (equation [2]) can become significantly larger at radii just beyond \( r_{core} = 10^{11} R_{11} \) cm. This jump in \( \Gamma_h \) is absent.
in Matzner’s (2002) treatment, which approximates with an unvarying $\rho \propto r^{-2}$ dependence the entire density profile on either side and across the He-H transition. A density drop steeper than $r^{-2}$ is however expected at this core-envelope transition for radiative envelopes (Eq. [1]), and is a distinctive feature of the numerical pre-collapse models employed above. Using equation (2) for the Lorentz factor of the entire cork in an H-envelope, the additional crossing time can be much much smaller than the core crossing time already incurred, $t_H \sim r_H / 2 c \Gamma_h^2 \ll t_{\text{core}}$ (Mészáros & Rees, 2001), as long as the envelope is not too extended, $r_H \lesssim \text{few} \times 10^{12} \text{ cm}$, e.g. for blue supergiants (BSG). This is independent of whether a small fraction of the outermost cork mass is accelerated across the bow shock, $\theta \sim \theta_{r}$. The comoving width of the shocked stellar plasma is obtained by balancing the mass flux with the tangential flux of particles leaving the cylinder of (cork frame) height $\Delta_s$ and radius $\theta r$ of shocked plasma, $\sim 2 \pi \theta r \Delta_s c_s \rho'$, where $c_s$ and $\rho'$ are the post-shock speed of sound and density respectively. Using $c_s = c / \sqrt 3$ and $\rho' = 4 \Gamma_h \rho$ for the relativistic ($\Gamma_h \gg 1$) case, which from now on we take as approximately valid for all cases considered, we obtain $\Delta_0 \approx 0.2 \theta r$. The Thomson optical depth of the shocked stellar plasma is thus

$$\tau_{T,s} \approx \begin{cases} 1.5 \times 10^4 \theta_{-1} L_{52}^{1/4} r_{12.5}^{1/2} \rho_{-7}^{3/4}, & \text{H} ; \\ 2.7 \times 10^6 \theta_{-1} L_{52}^{1/4} r_{11}^{1/2} \rho_{-3}^{3/4}, & \text{He} ; \\ 1.5 \times 10^8 \theta_{-1} L_{52}^{1/4} r_{10}^{1/2} \rho_{0}^{3/4}, & \text{CO} . \end{cases} \quad (4)$$

Here, $\theta = 0.1 \theta_{-1}$. The cork temperature is

$$T_r \approx \begin{cases} 1.6 L_{52}^{1/8} r_{12.5}^{-1/4} r_{0}^{1/8}, & \text{H} ; \\ 12 L_{52}^{1/8} r_{11}^{-1/4} r_{0}^{1/8}, & \text{He} ; \\ 50 L_{52}^{1/8} r_{10}^{-1/4} r_{0}^{1/8}, & \text{CO} . \end{cases} \quad (5)$$

The corresponding (cork frame) energy carried by the cork is thus

$$E_0 \approx \begin{cases} 3.9 \times 10^{48} L_{52}^{3/4} \theta_{12.5}^{3} r_{12.5}^{2}, & \text{H} ; \\ 4.3 \times 10^{45} L_{52}^{3/4} \theta_{11}^{3} r_{11}^{2}, & \text{He} ; \\ 4.3 \times 10^{43} L_{52}^{3/4} \theta_{10}^{3} r_{10}^{2}, & \text{CO} . \end{cases} \quad (6)$$

3. **Jet emergence: X-ray precursor**
3.1. Dynamics

As the forward shock approaches the stellar edge it accelerates to relativistic velocity. At some finite depth $d = R - r$ it becomes causally disconnected from the backward shock. This occurs at the point where during a sound crossing time of the cork, $\delta t \approx \Gamma_h 0.4 \theta r / c_s$, the forward shock accelerates significantly. Since $\Gamma_h \propto r^{-1/4}$ (as long as the forward shock is causally connected to the backward one), the fractional change in the shock Lorentz factor is $\delta \Gamma / \Gamma \approx \delta \rho / 4 \rho = c \theta t d \ln \rho / dr \approx 0.4 \Gamma_h (c / c_s) \theta r (n / 4) / (R_s - r)$. Thus, the forward shock becomes disconnected at $d \equiv R_s - r \approx \Gamma_h (d / c) \theta r$, where $\delta \Gamma / \Gamma \approx 1$ (here $\Gamma_h (d)$ is the main cork Lorentz factor at depth $d$). Denoting by $\Gamma_s$ the value of $\Gamma_h$ given by Eq. (2) for $r = R_s / 2$ assuming the density profile of Eq. (1), we find $d / R_s \approx (\Gamma_s \theta) n / (n + 4)$ and $\Gamma_h (d) \approx \Gamma_s n / (n + 4)$. Assuming $\theta \approx 1 / 15$, the value inferred by Frail et al. (2001), we find that the cork is mildly relativistic at the onset of “runaway” for all the progenitors (He, BSG, C/O) considered above. The dependence of $\Gamma_h (d)$ on $\theta$ is not very strong, $\Gamma_h (d) \propto (d / R) - n / 4 \propto \theta - n / (n + 4)$. The stellar densities at “runaway” onset are $\sim 1 g / cm^3$, $\sim 10^{-3} g / cm^3$ and $\sim 10^{-7} g / cm^3$ for the C/O, He and BSG progenitors respectively.

As the forward shock reaches depth $d$, it accelerates and breaks through the stellar edge before the backward shock reacts to the rapid acceleration. During jet propagation in the envelope, the shocked cork plasma is pushed sideways, away from the jet path, on a time scale $\Gamma h \propto \rho^{-1/4}$ (as long as the forward shock is causally connected to the backward one), the fractional change in the shock Lorentz factor is $\sim \theta r / \sigma c$. Since the shocks are radiation dominated, the maximum Lorentz factor to which plasma is accelerated is smaller than that given by this expression for $\tau (x) = 1$. Using Eq. (4), we find that the maximum Lorentz factor is of order 10 for all progenitor types mentioned above.

Whether or not a fast, $\Gamma \sim 10$, shell is ejected ahead of the cork is unclear. As the forward shock accelerates and becomes disconnected from the driving jet "piston", it is likely to become unstable (as commonly found in the non-relativistic case, e.g. Sari, Waxman & Shvarts 2001). Moreover, if the progenitor plasma is magnetized, the magnetic field may also prevent large $\Gamma$
gradients. We therefore consider in the following sub-section X-ray emission from the slower, main
cork plasma. We briefly comment here on how a fast shell ahead of the cork may affect this X-ray
emission.

Photons emitted by the cork would overtake the fast shell, spend some time diffusing through
it, and then escape. Let us first consider the time delay introduced to photon arrival times seen
by a distant observer. We show below that the fast shell does not change its radius significantly
during the photon diffusion through it. The time delay may therefore be decomposed into two
separate contributions: A geometric time delay due to a change in the photon propagation
direction, which is assumed to take place instantaneously at the shell overtaking radius, and a
diffusion time delay due to the fact that the effective velocity of the photon during the time it
spends in the shell is smaller than c (by \( c/2\Gamma(x)^2 \)).

As shown below, the time scale of photon emission from the cork is \( t_0 \sim \theta R_s/c \). Photons
emitted radially from the cork at time \( t_1 \sim 2\Gamma(x)^2 t \) at time \( t_1 \sim 2\Gamma(x)^2 t \). For \( t \gtrsim t_0 \), a fast shell with \( \Gamma(x) > \theta^{-1/2} \) expands significantly by \( t_1 \),
\( ct_1/R_s \sim \Gamma(x)^2 \theta \). In this case, the spread in overtaking times between photons emitted radially
and no-radially from the cork, \( \sim \theta^2 R_s/c \), is small compared to \( t_0 \), and we may consider geometric
time delay of radial photons only. For an observer along the jet axis, the geometric time delay
between two photons emitted at time \( t \) and scattered towards the observer from different points
in the fast shell, one from a point along the line of sight and the other from the edge of the shell,
propagating at angle \( \theta \) with respect to the line of sight (we have shown above that \( \Gamma(x) < 10 \lesssim 1/\theta \)
so that such scattering is possible), is \( \sim 0.5\theta^2 t_1 \approx [\Gamma(x)\theta]\theta t \). Since \( \Gamma(x)\theta < 1 \), the time spread
introduced by this geometric time delay would not affect significantly the shape of the pulse
emitted by the cork plasma.

Let us now consider the diffusion time delay. For \( t \gtrsim t_0 \), the optical depth of the shell
at \( t_1 \) is \( \tau_1(x) \approx \tau(x)(ct_1/R_s)^{-2} \). Since the proper thickness of the fast shell is \( x/\Gamma(x) \) (due
to the shock compression), the photon diffusion time through the shell is \( \approx \tau_1 x/\Gamma(x)c \) in
the shell frame, corresponding to \( \delta t_{diff} \approx \tau_1 x/c \) in the star frame. The delay in photon
propagation (compared to free propagation) is \( \delta t_{prop} \approx \delta t_{diff}/2\Gamma(x)^2 \). For \( t > t_0 \) we thus find
\( \delta t_{prop}/t_0 \sim [\tau_{T,s}/(n+1)\theta^2](t/t_0)^{-2\Gamma(x)\theta(5n+4)/n} \). For \( n = 3 \), the diffusion time delay is small,
compared to \( t_0 \), for \( \Gamma(x) > [\tau_{T,s}/(n+1)\theta^2]^{3/38} \). Using Eq. \( 4 \), we conclude that this time delay
is small for \( \Gamma(x) \) \( > \) a few. The fractional change in the shell radius during photon diffusion,
\( \sim \delta t_{diff}/2\Gamma(x)^2 t \approx \delta t_{prop}/t < \delta t_{prop}/t_0 \), is also small, justifying our assumption that the shell
radius is approximately constant over a photon diffusion time.

The arguments given above demonstrate that the fast shell would not affect significantly the
pulse shape. Let us now consider its effect on the photon spectrum. The comoving post-shock
temperature decreases towards the stellar edge, \( T(x)^4 \propto \Gamma(x)^2 \rho(x) \propto \rho(x)^{1/2} \), and the apparent
temperature \( \Gamma(x)^2 \propto \Gamma(x)^{1/2} \). The apparent temperature of the fast shell is not much larger than
that of the cork, any expansion of the shell further reduces its temperature, and its energy content
is much smaller than that of the main cork. An inverse Compton contribution is also found to be much less energetic than other components (§5.2). Thus, we expect the fast shell to have little effect on the spectrum as well.

### 3.2. X-ray flash at the first shock emergence

We consider now the X-ray emission from the cork break-out. We assume that the cork expands at its speed of sound at the cork break-out time, $c_s \simeq c/\sqrt{3} = 0.58c$ in the relativistic case. This is the sound speed for a radiation-dominated gas, rarefaction fronts typically expanding at the speed of sound. As discussed before, at cork break-out the shock is at least mildly relativistic in the cases of interest here, so we use this limit from now on. For simplicity we replace the flattened cork (width = 0.4$r$ < diameter = 2$r$) with a sphere, and denote its radius by $\Delta_0 = 2r/3$, which has the same volume. (The spherical expansion description in the comoving frame is a rough but convenient approximation, which becomes increasingly justifiable as the cork expands beyond one e-folding of its original dimensions at the same speed in all directions.) The cork’s radius increases (in its comoving frame) as $\Delta = \Delta_0 x$, $\rho = \rho_0 x^{-3}$, $T_r = T_{r,0} x^{-1}$ and $\tau_T = \tau_{T,0} x^{-2}$. Subscripts 0 denote values at cork break-out time. Since the optical depth is very large, photons diffuse out of a thin skin depth at the edge of the cork. The width of the skin-depth layer out of which photons have escaped is $\ell_{\text{diff}} \simeq c\Delta/3\tau_T$, where $\Delta/\tau_T$ is the photon mean free path. We therefore have $\ell_{\text{diff}}/\Delta \simeq c\Delta/3\Delta \tau_T = (x/\tau_{T,0})^{1/2}(t/t_0)^{1/2}$, where $t_0 \equiv 3\Delta_0/c$. The amount of energy radiated up to time $t$ is

$$E_{\text{rad}} \simeq 4\pi\Delta^3 \ell_{\text{diff}} aT^4 = \frac{3E_0}{\tau_{T,0}^{1/2}} \left( \frac{t}{t_0} \right)^{1/2},$$

and hence the comoving luminosity is

$$L_{\text{rad}} \simeq \frac{3E_0}{2t_0^{3/2}} x^{-3/2} \left( \frac{t}{t_0} \right)^{-1/2}.$$  

For times $t \ll t_{\text{exp}} \equiv \Delta_0/c_s = (c/3c_s)t_0$, the expansion is not important, $x \simeq 1$, hence $L \propto t^{-1/2}$ and $T_r \simeq T_{r,0}$. At later times, $x \gg 1$, $L \propto t^{-2}$ and $T_r \propto t^{-1}$. We note that the speed of sound in the shocked jet plasma is always (even for $\beta_h \ll 1$) relativistic, so that the rarefaction wave crosses the shocked jet plasma much faster than it crosses the shocked stellar plasma. Since the internal energy stored in the shocked jet and stellar plasma are similar (from the momentum and energy conservation across the shock implied by the shock jump conditions), the expansion of the shocked jet plasma will accelerate the expansion of the shocked stellar plasma to a velocity larger by a factor $\sim \sqrt{2}$. Thus, for arbitrary $\beta_h$, whether sub-relativistic or relativistic, we can approximate
\[ t_{\text{exp}} \approx t_0 / 2\beta_h. \] The total energy radiated is thus
\[
E_{\text{tot}} \approx \frac{3E_0}{\sqrt{2\beta_h T_{r,0}}} \tag{10}
\]

One should keep in mind the potential limitations of the 1-D approximation used here, since in 2-D numerical calculations (e.g. Aloy et al., 2000, Zhang et al., 2002) the emergence of the reverse shock and rarefaction wave indicates the formation of a conical shape due to lateral expansion.

For the parameters we used here, the 1-D approximation provides a useful description as long as the jet has not moved beyond much beyond \( \sim \) For the parameters we used here, the 1-D approximation provides a useful description as long as the jet has not moved beyond much beyond \( \sim \)

For a point on the source-observer line of sight, the characteristic break-out timescale \( t_{\text{exp}} \) is shortened to \( t_{\text{exp}}^{\text{obs}} = t_{\text{exp}} / 2\Gamma_h = \Delta_0 / 2\Gamma_h c_s \approx 0.5 \theta r / 2\Gamma_h c_s \). The angular smearing of the light curve occurs on a timescale \( dt_{\text{ang}}^{\text{obs}} \approx \theta^2 r / 2c \), for which \( d\theta_{\text{ang}} / dt_{\text{exp}} = 5 \Gamma_h \theta c_s / 2c < 5 \Gamma_h / 2\sqrt{3} \). Since \( \theta < 1 \) and \( \Gamma_h \) is at most a few, we have \( d\theta_{\text{ang}} / dt_{\text{exp}} \ll 1 \) and at a distance \( d \) the flux \( f \sim L / d^2 \) of the observed pulse shape follows Eq. (11): \( f \propto t^{-1/2} \) for \( t < t_{\text{exp}}^{\text{obs}} \).

\[
\begin{align*}
\frac{t_{\text{exp}}^{\text{obs}}}{t_{\text{exp}}} &= \left\{ \begin{array}{ll}
2.2 L_{52}^{-1/4} \theta_{r,1} \gamma_{12,5} \rho_{-7} \theta_{-1}^{3/2} r_{11} \rho_{-3}^{1/4}, & \text{H} (11) \\
1.4 \times 10^{-1} L_{52}^{-1/4} \theta_{r,1} \gamma_{12,5} \rho_{-7} \theta_{-1}^{3/2} r_{11} \rho_{-3}^{1/4}, & \text{He} (s) \\
2.4 \times 10^{-2} L_{52}^{-1/4} \theta_{r,1} \gamma_{12,5} \rho_{-7} \theta_{-1}^{3/2} r_{11} \rho_{-3}^{1/4}, & \text{CO}
\end{array} \right.
\end{align*}
\]

and \( f \propto t^{-2} \) at later times (here \( d \) is distance of the source). The flux \( f_0 \) at \( t = t_{\text{exp}}^{\text{obs}} \) is approximately given by \( f_0 = \Gamma_h (3E_0 / \sqrt{2\pi T_{r,s}}) / (2t_{\text{exp}}^{\text{obs}}) \pi (d / \Gamma_h)^2 \) in the relativistic approximation, \( f_0 = \left\{ \begin{array}{ll}
2.2 \times 10^{-9} L_{52}^{1/8} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{7/8} r_{11} \rho_{-3}^{1/4} d_{28}^2, & \text{H} (12) \\
4.9 \times 10^{-11} L_{52}^{1/8} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{7/8} r_{11} \rho_{-3}^{1/4} d_{28}^2, & \text{He} (s) \\
2.1 \times 10^{-12} L_{52}^{1/8} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{7/8} r_{11} \rho_{-3}^{1/4} d_{28}^2, & \text{CO}
\end{array} \right. \)

The rise time of the pulse, and hence the time at which the flux peaks, is
\[
\frac{t_{\text{exp}}^{\text{obs}}}{t_{\text{exp}}} \approx dt_{\text{ang}}^{\text{obs}} \approx \theta^2 r / 2c = \left\{ \begin{array}{ll}
5.2 \times 10^{-1} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{3/4}, & \text{H} (13) \\
1.7 \times 10^{-2} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{3/4}, & \text{He} (s) \\
1.7 \times 10^{-3} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{3/4}, & \text{CO}
\end{array} \right.
\]

and the peak flux is
\[
\frac{f_{\text{peak}}}{f_0} = \left\{ \begin{array}{ll}
4.4 \times 10^{-9} L_{52}^{5/4} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{3/4}, & \text{H} (14) \\
1.4 \times 10^{-10} L_{52}^{5/4} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{3/4}, & \text{He} (s) \\
7.4 \times 10^{-12} L_{52}^{5/4} \theta_{r,1} \gamma_{12,5} \rho_{-7}^{3/4}, & \text{CO}
\end{array} \right. \]

4. Cork dynamics following break-out

At the time \( t = t_{\text{exp}} \) in the frame moving with Lorentz factor \( \Gamma_h \), the rarefaction wave arrives at the backward shock decelerating the jet; the pressure behind this shock drops, and it can no
longer decelerate the fast jet plasma. A new system of forward-backward shocks is formed, which propagates into the expanding cork plasma (see figure for a schematic description). As the second forward shock breaks through the expanding cork, a second X-ray flash is produced. We consider the cork dynamics following the jet emergence in the relativistic limit, an approximation which is increasingly well satisfied.

### 4.1. Second shock

In the original frame of the shocked cork, moving with $\Gamma_h$, the shocked plasma expands, following the penetration of the rarefaction wave, with velocity comparable to the speed of sound, $\approx c/\sqrt{3}$. Adding (relativistically) this velocity to $\Gamma_h$, we find that the cork expands, in the source frame, with $\Gamma_s \approx (\sqrt{3/2} + 1/\sqrt{2}) \Gamma_h = 2 \Gamma_h$. Due to the expansion, the proper density of the expanding cork drops as $\rho = \rho_0 x^{-3} = 4 \Gamma_h \rho x^{-3}$. Let us denote by $\Gamma_{h2}$ the Lorentz factor (in the source frame) to which the rarefied cork plasma is accelerated by the second shock driven by the jet. As the cork density decreases with time, the second shock accelerates. Balancing the pressure behind the new forward shock, $3P_{h2} = 4(\Gamma_{h2}/2\Gamma_h^2)^2 4 \Gamma_h \rho x^{-3} c^2 = 4 \Gamma_{h2}^2 \rho c^2 / 4 \Gamma_h x^3$ (assuming the shock is relativistic), with the pressure behind the new backward shock, $3P_r = 4(\Gamma_j/2\Gamma_{h2})^2 n_j m_p c^2$, we find that $\Gamma_{h2}$ is given by an expression similar to that determining $\Gamma_h$, with $\rho$ replaced by $\rho/4 \Gamma_h x^3$. Using Eq. (2) we therefore find

$$\frac{\Gamma_{h2}}{\Gamma_h} = (4\Gamma_h x^3)^{1/4}. \quad (15)$$

Note that if we had assumed that the new forward shock driven into the cork is not relativistic, pressure balance gives $\beta_{h2} = x^3/2 \Gamma_h^{1/2} / 2$ for the shock velocity (in the frame where cork plasma is at rest), which implies that the shock is indeed relativistic.

In the frame moving with $\Gamma_h$, the forward shock Lorentz factor is $\Gamma_s = \sqrt{2 \Gamma_{h2}/2 \Gamma_h} = (\Gamma_h x^3)^{1/4}$. The shock breaks through the cork at time $t$ for which the distance it travels, given by $\int_{t_{exp}}^{t} dt (1 - 1/2 \Gamma_s^2) c$, equals the thickness of the expanded cork, $x(t) \Delta_0$. For $\Gamma_h \to \infty$, $\Gamma_s \to \infty$ and second shock break out occurs when $x \Delta_0 = c(t - t_{exp}) = \sqrt{3} \Delta_0 (x - 2)$, i.e. for $x = 2\sqrt{3}/(\sqrt{3} - 1) = 4.7$. For finite $\Gamma_h$, crossing occurs at larger $x$, e.g. at $x = 5$ for $\Gamma_h = 4$. We therefore adopt $x = 5$ for the crossing time. Note, that in this estimate we have assumed that $\Gamma_{h2}$ is given by Eq. (2) throughout the second crossing. However, the cork is composed of shocked stellar plasma, and shocked jet plasma. Eq. (13) holds for propagation through the shocked stellar plasma, while shock propagation in the shocked jet plasma is faster, due to its lower density. However, since the shock crossing time for $\Gamma_h = 4$ ($x = 5$) is close to that obtained for $\Gamma_s \to \infty$, we neglect the small correction implied for the crossing time.

Following the second shock crossing, the new (proper) thickness of the shocked cork plasma is $\Delta_2 \approx x \Delta_0/[4(\Gamma_{h2}/2\Gamma_h^2)] = (x_c/4\Gamma_h)^{1/4} \Delta_0$, where $x_c \approx 5$ is the value of the expansion factor at shock break-out. The resulting second X-ray flash properties are estimated in §5, following the
same reasoning of §3. We give here only the estimates for the dynamical cork parameters following
the second crossing:
\[
\frac{t_{\text{exp}2}}{\Delta_2} = \frac{\Delta_2}{\Delta_0} = \left( \frac{x_c}{4 \Gamma_h} \right)^{1/4},
\]
and
\[
t_{\text{exp}2}^\text{obs} = \frac{t_{\text{exp}2}}{2 \Gamma_{h2}} = \frac{t_{\text{exp}2}}{2 \sqrt{x_c} \Gamma_{h2}} = \begin{cases}
4 \times 10^{-1} L_{52}^{-3/8} \rho_{-7}^{3/8} \theta_{-11}^{7/4} \rho_{-3}, & \text{H;}
3 \times 10^{-2} L_{52}^{-3/8} \rho_{-7}^{3/8} \theta_{-11}^{7/4} \rho_{-3}, & \text{He;}
8 \times 10^{-3} L_{52}^{-3/8} \rho_{-7}^{3/8} \rho_{0}, & \text{CO.}
\end{cases}
\]

The proper thickness \(\Delta_2\) given by Eq. (16) is determined by the difference between the
propagation speed of the (second) shock and the speed of the fluid behind the shock. This thickness, which is
essentially the product of the speed difference and the shock life time, therefore grows with shock
life time. The proper thickness saturates, i.e. ceases to increase, when the mass flux across the
shock equals the tangential mass flux (which is proportional to the thickness). In §2, we have
determined the proper thickness \(\Delta_0\) of the shocked cork plasma by balancing the two mass fluxes.
Using the same argument here would have given \(\Delta_2 = \Delta_0\). However, Eq. (16) gives \(\Delta_2 < \Delta_0\),
which implies that the \(\Delta_2\) does not reach its asymptotic value during shock crossing.

Plasma expansion in the frame moving with \(\Gamma_{h2}\) is not isotropic. Following the first shock
break-out, the plasma expands roughly isotropically in the frame moving with \(\Gamma_h\), to which we
refer in what follows as the "isotropic cork frame". As the second shock propagates through
this expanding plasma, the flow ahead of the shock is not uniform, and the geometry of the
shock front is influenced by the shape of fluid streamlines ahead of the shock: the shock will no
longer propagate radially in the source frame. This situation is schematically described in figure
2. Since the Lorentz factor of the second shock, with respect to the fluid ahead of the shock, is
not very large, see Eq. (15), we expect a large modification of the shock front geometry due to
the non-uniform flow ahead of the shock. Assuming uniform pressure behind the shock implies
uniform velocity of the shock front with respect to the fluid velocity ahead of the shock, i.e. radial
shock expansion in the isotropic cork frame (moving with \(\Gamma_h\)), where the pre-shock fluid expands
isotropically. Following the second shock crossing, therefore, the shocked cork plasma fills, in the
isotropic cork frame, a semi-spherical shell of proper thickness \(\Delta_2\). This shell expands radially in
the isotropic cork frame, with a Lorentz factor \(\Gamma_{h2}/2 \Gamma_h\). The fluid propagating along the jet axis
propagates in the source frame with Lorentz factor \(\Gamma_{h2}\), and expands over an observed expansion
time given by Eq. (17).

4.2. Third shock

Following the second shock break-out, a second rarefaction wave propagates into the newly
shocked cork, following which a third shock crosses the rarefied cork. We denote by \(\Gamma_{h3}\) the
Lorentz factor in the source frame to which the rarefied cork plasma along the jet axis is
accelerated by the third shock. Here too, we expect the third shock to propagate radially,
with Lorentz factor $\Gamma_{h3}/2\Gamma_h$, in the isotropic cork frame. We define again the expansion factor as $x = 1 + c_s t/\Delta_2$, where $t$ is the proper time, measured in the fluid rest frame from second shock break-out. Time $\tilde{t}$ measured in the isotropic cork frame is related to the proper time through $\tilde{t} = (\Gamma_{h2}/2\Gamma_h)t$. The radius of the expanding shell in the isotropic cork frame at the second shock break-out is $R \approx x_c c_s t_{\text{exp}} = x_c \Delta_0 \approx 2\delta r$. This radius grows with time to $R + \tilde{t}c \approx R + (\Gamma_{h} x_c^3)^{1/4} c t/\sqrt{2} = R[1 + \sqrt{3/2}(\Gamma_{h} / x_c)^{1/4} t/t_{\text{exp}}] = R[1 + (\sqrt{3/2}) t/t_{\text{exp}2}] \approx x R$. Thus, the proper density of the expanding cork is $\rho = \rho_1 x^{-3} = 4(\Gamma_{h2}/2\Gamma_h') 4\Gamma_h \rho(x_c)^{-3} = 4\Gamma_{h2} \rho(x_c)^{-3}$. Balancing again the pressure behind the new forward shock, $3P_{h3} = 4(\Gamma_{h3}/2\Gamma_h')^2 4\Gamma_h \rho(x_c)^{-3} c^2 = 4\Gamma_{h3}^2 \rho c^2 / 4\Gamma_{h2} (x_c)^3$ (assuming a relativistic shock), with the pressure behind the new backward shock, $3P_h = 4(\Gamma_j/2\Gamma_{h3})^2 n_j m_p c^2$, we find that $\Gamma_{h3}$ is given by an expression similar to that determining $\Gamma_h$, with $\rho$ replaced by $\rho/4\Gamma_{h2}(x_c)^3$. Using Eq. (2) we therefore find

$$\frac{\Gamma_{h3}}{\Gamma_h} = (4\Gamma_{h2} x_c^3)^{1/4} = 2^{5/8} x_c^{15/16} x_c^3 / 4\Gamma_h^{5/16}. \quad (18)$$

If we had assumed that the new forward shock is not relativistic, pressure balance would give $\beta_{h3} = 0.5 x_c^{3/8} x_c^3 / 2 \Gamma_1^{1/8}$, which implies that the shock is relativistic. Arguments similar to those presented above imply that the third shock crossing also occurs at $x = x_c \approx 5$. At the end of the third shock crossing we therefore have

$$\frac{t_{\text{exp}3}}{t_{\text{exp}}} = \frac{\Delta_3}{\Delta_0} = \left( \frac{x_c}{4\Gamma_h} \right)^{5/16}, \quad (19)$$

and

$$\frac{t_{\text{obs}3}}{t_{\text{obs}}^{\text{exp3}}} = \frac{t_{\text{exp}3}^{\text{obs}}}{2\Gamma_{h3} x_c^{11/8} (4\Gamma_h)^{5/8}} = \begin{cases} 7.5 \times 10^{-2} L_{52}^{-13/32} \theta_{-1712}{1/5} \rho_{-7}^{9/16}, & \text{H}; \\ 7.0 \times 10^{-3} L_{52}^{-13/32} \theta_{-1711}{9/16} \rho_{-3}^{13/32}, & \text{He}; \\ 1.7 \times 10^{-3} L_{52}^{-13/32} \theta_{-1710}{9/16} \rho_{-3}^{13/32}, & \text{CO}. \end{cases} \quad (20)$$

Finally, we note that at the end of the third shock crossing, the radius of the expanded cork, in the isotropic cork frame, is $x_c R = x_c^2 \Delta_0$, and the distance $\delta r$ propagated by the cork along the jet axis is comparable to the stellar radius, $\delta r \approx c \Gamma_{h2} x_c t_{\text{exp}2} \approx \sqrt{3} x_c^2 \Gamma_h \Delta_0 \approx \Gamma_h \theta_{-1} r$.

Following the third rarefaction wave, the plasma is accelerated to $\Gamma'_{h3} \approx 2\Gamma_{h3} \approx 50\Gamma_h^{21/16}$, for which $\Gamma_j/2\Gamma_{h3} \approx \Gamma_j/100\Gamma_h^{21/16}$. Thus, following the third shock crossing the remnants of cork plasma in the jet path are accelerated to a high Lorentz factor. A strong fourth shock wave will be driven by the jet into this plasma only for $\Gamma_j \gg 100$.

5. X- and $\gamma$-ray pulses from the 2nd and 3d shocks

5.1. Thermal pulses

The thermal emission following the second and third shock crossings can be estimated using arguments similar to those of §3. The energy density in the shocked cork plasma is proportional to
\[ T_2 = T_r (\Gamma h_2 / \Gamma h_1)^{-1/2} \text{ and } T_3 = T_r (\Gamma h_3 / \Gamma h_1)^{-1/2}, \text{ where } T_r \text{ is given by Eq. (5). Using Eqs. (15) and (18) we obtain for the temperature of the observed pulses}

\[
\Gamma h_2 T_2 = (4 \Gamma h_1)^{1/8} x_c^{3/8} \Gamma h_1 T_r = \begin{cases} 
6.2 L_{52}^{13/32} / r_{12.5}^{13/16} \rho_{-7}^{5/32}, & \text{H;} \\
2.3 \times 10^4 L_{52}^{13/32} / r_{11}^{13/16} \rho_{-3}^{5/32}, & \text{He; keV,} \\
5.1 \times 10^4 L_{52}^{13/32} / r_{10}^{13/16} \rho_0^{5/32}, & \text{CO,}
\end{cases}
\]

\[
\Gamma h_3 T_3 = 2^{5/16} x_c^{27/32} \Gamma h_1 T_r = \begin{cases} 
1.4 \times 10^4 L_{52}^{53/128} / r_{12.5}^{53/64} \rho_{-7}^{21/128}, & \text{H;} \\
5.2 \times 10^4 L_{52}^{53/128} / r_{11}^{53/64} \rho_{-3}^{21/128}, & \text{He; keV,} \\
1.1 \times 10^4 L_{52}^{53/128} / r_{10}^{53/64} \rho_0^{21/128}, & \text{CO.}
\end{cases}
\]

Radiation emitted following the second shock crossing arrives at a distant observer lying along the jet axis from a cone around the jet axis of opening angle \(1/(\Gamma h_2/2 \Gamma h_1) = 2 \Gamma h/\Gamma h_2\) in the isotropic cork frame, where the shell radius is \(R = x_c \Delta_0\). The angular time spread of the pulse is therefore given by \(dt_{\text{ang2}}^{\text{obs}} = (2 \Gamma h/\Gamma h_2)^2 R / 2 (2 \Gamma h) c = \Gamma h x_c \Delta_0 / \Gamma h_2 c\). Comparing this time to the observed expansion time, \(t_{\text{exp}}^{\text{obs}} = \sqrt{3} \Delta_2 / 2 \Gamma h_2 c = \sqrt{3} x_c \Gamma h_2 \Delta_0 / 2 \Gamma h_2^3 c\), we find \(dt_{\text{ang2}}^{\text{obs}} / t_{\text{exp}}^{\text{obs}} = 2 / \sqrt{3} \approx 1\). Thus, the second pulse is “smeared” over a duration \(dt_{\text{ang2}}^{\text{obs}}\). Note that, had we assumed radial expansion in the source frame, the angular time spread would have been \(r / 2 \Gamma h_2 c = (r / 2 x_c \Gamma h_2 \Delta_0) dt_{\text{ang2}}^{\text{obs}} \approx (2.5 / \Gamma h \theta_{-1}) dt_{\text{ang2}}^{\text{obs}}\). Thus, the resulting pulse duration is not sensitive to the detailed geometry of the shock front.

The proper energy in the cork plasma following the second shock crossing is \(E_2 = 2 \pi R^2 \Delta_2 (a T^2) = 2 \pi (x_c \Delta_0)^2 (\Gamma h x_c \Delta_0 / \Gamma h_2) a (\Gamma h_2 / \Gamma h_1)^{-2} T_r^4 = 2 \pi \Delta_3^3 (\Gamma h x_c / \Gamma h_2)^3 a T_r^4 \approx 0.3 (\Gamma h x_c / \Gamma h_2)^3 E_0\). Since the optical depth following the first crossing is reduced, \(\tau_{T,s2} = x_c^{-2} \tau_{T,s1}\), the flux of the second pulse is \(f_2 \approx \Gamma h_2 (3 E_2 / \sqrt{2} T_{s2}) / t_{\text{exp}}^{\text{obs}} \approx 0.3 x_c^3 f_0\),

\[
f_2 \approx 0.3 x_c^3 f_0 = \begin{cases} 
8.6 \times 10^{-8} L_{52}^{11/8} \theta_{-1}^{3/2} / r_{12.5}^{-13/4} \rho_{-7}^{1/4} d_{28}^{7/8}, & \text{H;} \\
6 \times 10^{-10} L_{52}^{11/8} \theta_{-1}^{3/2} / r_{11}^{-13/4} \rho_{-3} d_{28}^{7/8}, & \text{He; erg cm}^{-2} \text{s}^{-1}, \\
1.1 \times 10^{-11} L_{52}^{11/8} \theta_{-1}^{3/2} / r_{10}^{-13/4} \rho_0 d_{28}^{7/8}, & \text{CO.}
\end{cases}
\]

The duration of this pulse is given by Eq. (17).

Radiation emitted following the third shock crossing arrives at a distant observer lying along the jet axis from a cone around the jet axis of opening angle \(1/(\Gamma h_3 / 2 \Gamma h_1) = 2 \Gamma h / \Gamma h_3\) in the isotropic cork frame, where the shell radius is \(R = x_c^2 \Delta_0\). The angular time spread of the pulse is therefore given by \(dt_{\text{ang3}}^{\text{obs}} = (2 \Gamma h / \Gamma h_3)^2 R / 2 (2 \Gamma h) c = \Gamma h x_c^2 \Delta_0 / \Gamma h_3^2 c\). Comparing this time to the observed expansion time, \(t_{\text{exp}}^{\text{obs}} = \sqrt{3} \Delta_3 / 2 \Gamma h_3 c = \sqrt{3} x_c^2 \Gamma h_3 \Delta_0 / 2 \Gamma h_3^2 c\), we find \(dt_{\text{ang3}}^{\text{obs}} / t_{\text{exp}}^{\text{obs}} = 2 / \sqrt{3} \approx 1\). Thus, the third pulse is “smeared” over a duration \(dt_{\text{ang3}}^{\text{obs}}\). If we had assumed radial expansion in the source frame, the angular time spread would have been \(r / 2 \Gamma h_3 c = (r / 2 x_c^2 \Gamma h_3 \Delta_0) dt_{\text{ang3}}^{\text{obs}} \approx (2.5 / x_c \Gamma h \theta_{-1}) dt_{\text{ang3}}^{\text{obs}}\). Thus, the resulting pulse duration is again not sensitive to the detailed geometry of the shock front.
The flux of the third pulse is

\[ f_3 \approx 0.3x_c^6 f_0 = \begin{cases} 
1.1 \times 10^{-5} L_{52}^{11/8} \theta_{-1}^{3/2} / r_{12.5}^{5/4} \rho_7^{-d_{28}/7}, & \text{H;} \\
7.7 \times 10^{-8} L_{52}^{11/8} \theta_{-1}^{3/2} / r_{11}^{5/4} \rho_0^{-d_{28}/7}, & \text{He;} \\
1.4 \times 10^{-9} L_{52}^{11/8} \theta_{-1}^{3/2} / r_{10}^{5/4} \rho_0^{-d_{28}/7}, & \text{CO.} 
\end{cases} \]  

The X-ray pulses from the three shocks are schematically shown in Figure 3, appearing as precursors to the main burst emission.

### 5.2. Non-thermal emission

As the shock approaches the shell edge, where the optical depth ahead of the shock drops to \( \sim 1 \), the radiation will escape and the shock will no longer be radiative-dominated. It will most likely become collisionless. Waxman & Loeb (2001) have shown that, for a mildly relativistic shock, the ratio of electro-magnetic instability growth rate and ion-ion (Coulomb) collision rate most likely become collisionless. Waxman & Loeb (2001) have shown that, for a mildly relativistic shock, the radiation will escape and the shock will no longer be radiation dominated. It will then be collisionless as well. For the BSG progenitor, the optical depth of the cork shell during third shock crossing is reduced to a few. Thus, \( \tau_{T,s} \approx 2 \) for a fourth shock crossing takes place, i.e., if \( \Gamma_j \gg 100 \), the fourth shock will be collisionless as well. For the BSG progenitor, the optical depth of the cork shell during third shock crossing is reduced to \( \sim 10 \). In this case, therefore, a significant fraction of the internal energy of the cork may be emitted as radiation from electrons accelerated to a non-thermal distribution by the collisionless shock.

We estimate below the non-thermal emission from the third shock as it becomes collisionless. In order to derive an estimate that is (nearly) independent of the details of the preceding cork shocks dynamics, we use the following line of arguments. The isotropic-equivalent mass of plasma shocked by the collisionless shock is \( M_{CL} \approx 4\pi (\Gamma_h \theta_{-1} r)^2 \tau m_p / \sigma_T \), where we have taken \( r_{CL} = \Gamma_h \theta_{-1} r \) as the shock radius (due to expansion of the plasma during the 3rd shock crossing, see [Figure 3] and \( \tau \sim 1 \) is the optical depth ahead of the shock at the point it becomes collisionless (\( \tau m_p / \sigma_T \) is the corresponding column density). We have shown that the Lorentz factors of the shocks, in the frame at which the plasma ahead of the shocks is at rest, are of order a few. Thus, the isotropic-equivalent thermal energy generated by the collisionless shock is

\[ E_{CL} \approx \Gamma_j \Gamma_i M_{CL} c^2 = \begin{cases} 
7.7 \times 10^{50} \tau \Gamma_i \Gamma_j, & \text{H;} \\
2.6 \times 10^{47} \tau \Gamma_i \Gamma_j, & \text{He;} \\
8.6 \times 10^{44} \tau \Gamma_i \Gamma_j, & \text{CO.} 
\end{cases} \]
where $\Gamma_i \sim a$ few is the collisionless shock Lorentz factor (in the plasma frame). We have shown in §4 that the proper thickness of the shocked cork shell following each shock passage is close to $\Delta_0$. The proper energy density behind the collisionless shock is therefore $u_{CL} \approx (E_{CL}/\Gamma_j)/4\pi r_{CL}^2(\Delta_0/\tau_{CL})$, where $\tau_{CL} \sim 10$ is the total optical depth of the shell at the stage where the collisionless shock is formed. Assuming that a fraction $\xi_e (\xi_B)$ of the thermal energy is carried by accelerated electrons (magnetic field), the characteristic frequency of synchrotron photons emitted by the electrons, accelerated to a characteristic Lorentz factor $\gamma_e \approx \xi_e \Gamma_i (m_p/m_e)$, is

$$h\nu_{sym} \approx \begin{cases} 
7.9\Gamma_i^{5/2}\xi_e^2\sqrt{r_{CL}\xi_B\Gamma_j,2.5}\theta_{-1/2}^{-1/2}r_{12.5}^{-1/2}, & \text{H;} \\
4.3 \times 10^{14}\Gamma_i^{5/2}\xi_e^2\sqrt{r_{CL}\xi_B\Gamma_j,2.5}\theta_{-1/2}^{-1/2}r_{11}^{-1/2}, & \text{He; MeV.} \\
1.4 \times 10^{2} \Gamma_i^{5/2}\xi_e^2\sqrt{r_{CL}\xi_B\Gamma_j,2.5}\theta_{-1/2}^{-1/2}r_{10}^{-1/2}, & \text{CO.} 
\end{cases}$$

(26)

Thus, the third thermal (hard) X-ray pulse is accompanied by a non-thermal MeV gamma-ray pulse, with similar energy flux and duration.

An IC component is also expected, due to the thermal X-ray photons emitted from the cork which are up-scattered by the fast jet, $\Gamma_j \sim 10^2$, as it emerges from the cork (Ramirez-Ruiz, et al. 2002). The fluence of this IC component is significantly lower than the value estimated in the above reference, which was based on a simplified treatment assuming that all the thermal X-ray photons in the cork are up-scattered by the relativistic jet. However, as shown in §3.2, only a fraction $\tau_{T,0}^{-1/2} \ll 1$ of the thermal X-ray photons escape the cork and are available for up-scattering [see Eq. (4)]: the value of $\tau_{T,0}^{-1/2}$ ranges from $10^{-2}$ for the BSG progenitor to $10^{-4}$ for the CO progenitor [see Eq. (4)]. Also, as shown in §3.2, the fast jet emerges from the cork only after third shock crossing, at a time (measured in the star’s frame) $\approx \Gamma_{h2}c\Delta_0/c$ after the first cork break-out. This time is much longer than the transverse light crossing time of the jet, $\sim \Delta_0/c$. Thus, most of the X-ray photons escape out of the jet’s path prior to the emergence of the jet from the cork. We therefore conclude that the non-thermal emission is dominated by the collisionless emission given by Eqs. (25) and (26).

A second IC component may be produced if there is a $\Gamma \sim 10\Gamma_1$ fore-runner shell ejected ahead of the main cork, as discussed in §3.1, from the up-scattering of stellar photons by the fore-runner. The number density of stellar photons drops as $r^{-2}$, so most of the fluence is produced by scattering of stellar photons near $R_*$, where $R_*$ is the stellar radius. The (isotropic equivalent) energy of this IC component is $\sim L_{\star}(R_*/c)^2 \sim 10^{37}\Gamma_1^2L_*/L_\odot$ erg, where $L_\star$ is the stellar luminosity. This is much smaller than other high energy components, such as equation (25).

6. Discussion

We have shown that the emergence of a jet in a collapsar model of GRB leads to a series of successive, increasingly shorter and harder thermal X-ray pulses. These are caused by successive
cycles of shock waves and rarefaction waves reaching the outer and inner ends of the “cork” of stellar material being pushed ahead of the jet as it passes beyond the boundary of the stellar envelope. The Lorentz factor of the main bulk of the cork increases with each succeeding and increasingly relativistic shock that goes through it. A small fraction of the cork mass may be accelerated to larger Lorentz factors and run ahead of the cork, without changing significantly the development of the thermal pulses from the main bulk of the cork.

The expansion and acceleration of the main bulk of the cork lead to a decrease of the cork scattering optical depth, photon diffusion times and expansion times in the observer frame for the successive shocks. As a result the successive shocks have increasingly higher bolometric fluences and shorter durations, as well as harder peak photon energies. However, for observations in a fixed low energy X-ray band, e.g. 2 keV, the specific fluence in erg/cm$^2$/keV would be reduced by a Rayleigh-Jeans factor $(E_{\text{obs}}/E_{pk})^2$ and would appear almost constant or slowly declining as the pulse number increases. On the other hand, in a hard X-ray detector, e.g. $\gtrsim$ 20 keV, the successive pulses would show a steeply increasing fluence.

The results discussed here are based on analytical 1-D calculations in the relativistic limit. As argued in § 2 and in § 3, the approximations inherent in such an analytical treatment are reasonable for the range of parameters considered, but the flows considered are quite complex, and definitive results must await confirmation from more accurate numerical simulations. Current 2-D relativistic collapsar jet simulations (e.g. Aloy et al. 2000, Zhang et al., 2002) do not so far have the dynamic range and resolution necessary to distinguish multiple shocks and rarefaction waves upon emergence of the jet, but provide valuable informations about the overall jet dynamics. The approximate analytical treatment presented here fulfill in the meantime an exploratory role, and provide insights both for future numerical and observational developments.

The temporal structure discussed provides distinct features, which should help to identify the phenomenon. We have argued (§3) that since jets are likely to accelerate to significantly relativistic velocities as they enter a much lower density H-envelope, the crossing time for a blue supergiant envelope may be only slightly longer than the core crossing time $t_{\text{core}} \sim 30r_{11}$ s for He or CO dwarf stars. The initial rise-time of the first pulse leading to the peak flux, given by the angular smearing time, is $t_{\text{obs}}^{pk} \sim [500, 20, 2]$ ms for a blue supergiant (H) star, a He star and a CO star, occurring while the cork has not yet had time to expand. This is followed by a decay $f \propto t^{-1/2}$ lasting an expansion time $t_{\text{exp}}^{\text{obs}} [2, 0.15, 0.025]$ s for the [H, He, Co] cases. Thereafter the flux drops as $f \propto t^{-2}$. The subsequent pulses have similar rise and decay times, given approximately by (increasingly shorter) observer-frame expansion times.

For stars of greater compactness (smaller radius) the characteristic bolometric fluxes, timescales and fluences of each pulse are lower and shorter while the peak temperatures are higher. The typical fluences from a Hubble distance $d \sim 10^{28}$ cm range from $F \sim [5 \times 10^{-9}, 7 \times 10^{-12}, 5 \times 10^{-14}]$ erg/cm$^2$ for the first pulse, to $F \sim [8 \times 10^{-7}, 5 \times 10^{-10}, 2 \times 10^{-12}]$ erg/cm$^2$ for the third pulse, while the peak temperatures range from $T_{pk}^{\text{obs}} \sim [1.6, 12, 50]$ keV for the first pulse, to
$T_{pk}^{\text{obs}} \sim [14, 52, 110] \text{ keV}$ for the third pulse in [H, He, CO] stars respectively.

After the third shock, the cork will have reached Lorentz factors comparable to the observationally inferred Lorentz factors in bursts ($\Gamma \sim 100$). This shock may become collisionless, leading also to an additional non-thermal component of energy and duration comparable to the thermal third pulse, with characteristic photon energy $E_\gamma \sim [8, 45, 140] \text{ MeV}$ for [H, He, CO] stars.

With the fluences calculated here it is apparent that it would be easier to detect the X-ray pulses from extended GRB progenitors, such as blue supergiant (H) stars. The more compact progenitors (He or CO stars) would have lower fluences and be harder to detect, except for nearby objects, in which case they would be distinguishable from blue supergiant progenitors through their shorter peak durations and harder spectra. The characteristic precursor thermal pulses, including the third thermal and non-thermal pulses described here, would precede the conventional MeV range emission by an appreciable timescale $t_{\text{exp}}^{\text{obs}} \sim 2.2 L_{52}^{-1/2} \theta_{-1}^{3/2} r_{12.5}^{3/2} \rho_{-7}^{1/4} \text{ s}$ for blue supergiant (H) progenitors, or by shorter timescales $\sim 0.15, 0.025 \text{ s}$ for He or CO progenitors.

It is conventionally assumed that the conditions for the usual successful GRB to occur is that the central engine powers the jet for timescales $t_j$ longer than the stellar crossing time $t_{\text{core}} \sim 30 r_{11} \text{ s}$. However, there may be cases where the jet just breaks through the outer envelope of the star (whether it be a He, CO or H BSG star), and does not live much longer afterwards (e.g. $t_j \lesssim 30 \text{ s}$). In this case, electromagnetic detectors will see only the thermal X-ray pulses and the hard non-thermal gamma-ray pulse ($\gtrsim 10 \text{ MeV}$, §5.2), which last seconds or less. These would be a new class of objects, perhaps related to X-ray flash bursts and/or to short GRBs, especially if such events are more common, and their distance is smaller.

The characteristic timescales as well as the ratios of the amplitudes and hardnesses of the pulses differ substantially, depending on the density and extent of the stellar envelope, which provides a potentially valuable diagnostic for pinning down the conditions in the pre-burst stellar progenitor. Instruments to be flown in the next several years, such as Swift, GLAST, AGILE and others, should be able to detect such precursor signals in some bursts, and provide valuable clues concerning the GRB mechanism and their progenitors.

Fig. 1.— The top panel presents a schematic description of the double shock structure at the head of the jet, as seen in the frame where the shocked plasma is at rest, during jet propagation within the star. The dot-dashed line shows the pressure distribution. The bottom panel presents a schematic description of the flow after forward-shock break-out. A rarefaction wave propagates backward into the shocked plasma, and the plasma ahead of this wave expands with velocity comparable to the speed of sound. When the rarefaction wave reaches the backward shock, a new double-shock structure similar to that shown on the top panel is formed, propagating through the expanding shocked plasma.
Expanding cork plasma

Fig. 2.— A schematic description of the flow during second shock propagation through the cork, as seen in the "isotropic cork frame" moving with $\Gamma_h$.
