Abstract

The influence of alpha clustering on nuclear reaction dynamics is investigated using the giant dipole resonance (GDR) lineshape studies in the reactions $^{20}$Ne ($E_{\text{lab}}$=145,160 MeV) + $^{12}$C and $^{20}$Ne ($E_{\text{lab}}$=160 MeV) + $^{27}$Al, populating $^{32}$S and $^{47}$V, respectively. The GDR lineshapes from the two systems are remarkably different from each other. Whereas, the non alpha-like $^{47}$V undergoes Jacobi shape transition and matches exceptionally well with the theoretical GDR lineshape estimated under the framework rotating liquid drop model (RLDM) and thermal shape fluctuation model (TSFM) signifying shape equilibration, for alpha cluster $^{32}$S an extended prolate kind of shape is observed. This unusual deformation, seen directly via $\gamma$-decay for the first time, is predicted to be due to the formation of orbiting di-nuclear configuration or molecular structure of $^{16}$O+ $^{16}$O in $^{32}$S superdeformed band.

PACS numbers: 24.30.Cz,24.60.Dr,25.70.Gh
In recent years, there have been intense theoretical and experimental efforts \cite{1, 2}, to search for highly (super/hyper) deformed (SD/HD) nuclear systems. There are indications that such highly deformed shapes are likely to be observed in light $\alpha$-like systems ($A_{CN} \sim 20-60$) at higher angular momenta (typically, $\gtrsim 15\hbar$) and excitation energies (typically, $\gtrsim 40$ MeV). Experimentally, large deformations were observed in $^{36}\text{Ar}$ \cite{3} and $^{40}\text{Ca}$ \cite{4}, where the deformations were studied using $\gamma$-spectroscopic techniques. In recent times, experimental indications of hyperdeformation have also been reported in the decay of $^{56}\text{Ni}$ \cite{5, 6} and $^{60}\text{Zn}$ \cite{7}, where charged particle spectroscopy was used to identify the ternary fission-like decay of hyperdeformed composites. Hyperdeformed shape in $^{36}\text{Ar}$ has also been predicted \cite{8}, however, it is not yet firmly established experimentally \cite{1}.

Such large deformations observed in light $\alpha$-like systems are believed to be due to the occurrence of either quasimolecular resonances or nuclear orbiting \cite{9}, which have the origin in $\alpha$-cluster structure of these nuclei. On the other hand, rapidly rotating light nuclei in general are likely to undergo Jacobi shape transition at an angular momentum value near the fission limit, where the shape changes abruptly from non-collective oblate to collective triaxial / prolate shape. Since it is possible for the light mass nuclei to attain very high angular velocities beyond the critical point for Jacobi transition without undergoing fission, existence of exotic shapes in nuclei with a large deformation becomes likely. Signatures of such shape transitions in $^{45}\text{Sc}$ \cite{10} and $^{46}\text{Ti}$ \cite{11, 12, 13} have been reported from the study of line shapes of giant dipole resonance (GDR) built on excited states. Recently, the Jacobi shape transition has been confirmed for $^{48}\text{Cr}$ \cite{14} from high-spin spectroscopy and corresponding theoretical calculation using the LSD liquid drop model \cite{15}. It is, therefore, relevant to explore the relationship between the shapes of the light $\alpha$-like systems and the corresponding Jacobi shapes, which would help in understanding the reaction dynamics of light $\alpha$-like systems and the role played by $\alpha$-clustering in determining the shape.

The aim of the present study is to make quantitative experimental estimation of the deformed shapes of light alpha and non-alpha systems using GDR lineshape studies and compare them with the corresponding predictions for equilibrium Jacobi shapes. For $\alpha$-like system, we have taken $^{20}\text{Ne} + ^{12}\text{C}$ system and for non-$\alpha$-like system, we have chosen $^{20}\text{Ne} + ^{27}\text{Al}$ system. The $^{20}\text{Ne} + ^{12}\text{C}$ system is well established orbiting system \cite{16}, and our previous studies on enhancement of fragment yield near the entrance channel \cite{17} as well as $\alpha$-spectroscopic studies \cite{18} have strongly indicated a highly deformed orbiting dinuclear
shape for this system. On the contrary, for non-alpha like $^{47}$V system, it is well established that there is no significant entrance channel effect and fusion-fission compound nuclear yield is dominant in accordance with the qualitative expectation from the number of open channels model $^{19, 20}$. Since $\alpha$-spectroscopic studies can only indicate effective deformation in an indirect way, it is worthwhile to complement the above studies with the investigation of nuclear shapes of the excited rotating systems through the GDR $\gamma$-decays in a more direct manner.

The GDR, linear oscillations of the protons and neutrons in the hot nucleus, occurs on a time scale that is sufficiently short. Thus, these can compete with other modes of nuclear decay. In addition, the resonance couples directly with the other nuclear degrees of freedom, such as shape degrees of freedom, and thus can provide information on the shape evolution of the nuclei at finite temperature and fast rotation. The resonance energy being proportional to the inverse of the nuclear radius, the GDR strength function splits in the case of deformed nuclei and the investigation of the strength distribution gives a direct access to nuclear deformations. Here, we report the experimental GDR strength functions for the hot, rotating composites formed in $^{20}$Ne + $^{12}$C and $^{20}$Ne + $^{27}$Al systems and show, for the first time, that, whereas the experimentally extracted shape for $^{20}$Ne + $^{27}$Al conforms to the predicted Jacobi shape, extracted shape of the $^{20}$Ne + $^{12}$C system is highly elongated (prolate) and does not conform to the corresponding Jacobi shape, clearly highlighting the difference between the reaction mechanisms in the two cases.

The $^{47}$V and $^{32}$S nuclei were formed by bombarding pure 1 mg/cm$^2$ thick $^{27}$Al and $^{12}$C targets with accelerated $^{20}$Ne beams from the K-130 cyclotron at the Variable Energy Cyclotron Centre, Kolkata, India. The initial excitation energy for $^{47}$V compound system was $E_x=108$ MeV corresponding to a projectile energy $E_{proj}=160$ MeV. Similarly the initial excitation energies for $^{32}$S nucleus were $E_x=73$ & 78 MeV corresponding to the projectile energies of $E_{proj}=145$ & 160 MeV. The corresponding critical angular momenta for $^{47}$V and $^{32}$S nuclei are $l_c=38\hbar$ and $24\hbar$ respectively, same as those extracted from previous complete fusion measurement by using the sharp cut-off approximation for $^{47}$V $^{21}$ and $^{32}$S $^{22}$. These values extend well beyond the critical angular momentum values of $29.6\hbar$ and $21.5\hbar$ at which the Jacobi transitions are predicted to occur for these nuclei(according to systematics $J_c = 1.2A^{5/6}$ $^{23}$). They are formed in identical conditions as in the previous charged particle experiment reported earlier $^{18}$. The experimental arrangement and technique was
similar to that described earlier \cite{24}. The high energy photons were detected at $\theta_\gamma = 55^\circ$ with a part of the LAMBDA (Large Area Modular BaF$_2$ Detector Array) spectrometer arranged in a $7 \times 7$ square matrix \cite{25}. An event-by-event information of the populated angular momentum was recorded using a 50 element BaF$_2$ based low energy $\gamma$-multiplicity filter in coincidence with the high energy photon events. The multiplicity filter was kept at a distance of 10 cm from the target which ensured the selection of higher part of the spin distribution. The schematic view of the experimental setup is shown in Fig.1. Time of flight (TOF) technique was used to eliminate neutrons while pulse shape discrimination (PSD) was adopted to reject pile-up events for the individual detector elements. The PSD and the TOF spectra for a single detector is shown in Fig.2 clearly indicating excellent rejection of neutrons and pile-up events.

The linearized GDR spectra from $^{47}$V (for two ang. mom. windows) and $^{32}$S (for two incident energies) are shown in Fig.3. The GDR lineshapes from the two systems are remarkably different, from which one usually gets in the case of a spherical or a near spherical system and indicate large deformations. The most striking feature in the case of $^{47}$V populated at $28\hbar$ & $31\hbar$ is the strong enhancement in $\gamma$-yield at $\sim 10$ MeV similar to one observed in $^{46}$Ti \cite{11} earlier. It is characteristic of a large deformation and the effect of coriolis splitting due to very high angular velocity in the system. Such very high angular velocities are usually achieved by the system normally beyond the Jacobi transition point. However, for $^{32}$S no such enhancement is seen though the nucleus is populated at spins well beyond Jacobi transition point. A 2-component GDR strength function fits the experimental data fairly well. The extracted parameters are given in table-I. The shape looks more like a highly extended prolate and is seen for the first time for this nucleus. The GDR lineshape for $^{47}$V, on the other hand, is more complex and a simple two or three component GDR strength function fails to describe the experimental observations. The linearized GDR lineshapes were extracted using a modified version of the statistical model code CASCADE \cite{24, 26}. For both the cases we have adopted the Ignatyuk level density prescription \cite{27} keeping the asymptotic level density parameter $\tilde{a} = A/8$ MeV$^{-1}$. The CASCADE calculations have been performed with the same parameters as used in the charged particle analysis except for the $\delta 1$ parameter in the case $^{32}$S. We have taken $\delta 1$ as $1.0 \times 10^{-3}$ in order to explain the low energy part of the $\gamma$ spectrum.

In order to interpret the extracted GDR strength functions in the entire $\gamma$-ray energy...

region (5-32 MeV) and to understand the equilibrium deformations in these hot and rotating nuclear systems, a calculation is performed for estimating the equilibrium shape of a nucleus by minimizing the total free energy under the framework of rotating liquid drop model (RLDM) and thermal shape fluctuation model (TSFM) for a given temperature $T$ and angular momentum $J$. Earlier, a similar model with a modified liquid drop parametrization (LSD Model) was used to extract the shape evolution of $^{46}$Ti and $^{48}$Cr [11, 14, 15].

The free energy for a hot rotating nucleus at a constant spin ($J$), in a liquid drop picture, can be written as [28],

$$ F(T, J, \beta, \gamma) = E_{LDM}(\beta, \gamma) - TS + \frac{J(J + 1)\hbar^2}{2(\omega.I.\omega)} $$

where

$$ \omega.I.\omega = I_{xx}\sin^2\theta\cos^2\phi + I_{yy}\sin^2\theta\sin^2\phi + I_{zz}\cos^2\theta $$
FIG. 3: (color online) (a) The experimental $\gamma$-spectra and extracted linearized GDR strength functions (b,c) for $^{47}$V for the two angular momentum windows. The dotted lines are the respective CASCADE predictions and the solid lines are the predicted line shapes from the free energy minimization technique. Same for $^{32}$S for two incident energies (d,e,f). The solid lines are the CASCADE predictions using 2-GDR components and the dotted lines are the predicted line shape from the free energy calculations.

is the moment of inertia about the rotation axis $\omega$. $I_{xx}$, $I_{yy}$, $I_{zz}$ are the principal rigid body moments of inertia and $S$ is the entropy of the system. The dependence of level densities on deformation and shell corrections are assumed to be small and neglected as the nuclear temperatures in this case are $\sim 3$ MeV. $E_{LDM}(\beta, \gamma)$ is the deformed liquid drop energy, calculated in terms of $\beta$ and $\gamma$, the intrinsic quadrupole deformation parameters [29-32]. The deformed moment of inertia can be written in Hill-Wheeler parametrization as, $I_{zz} = B_1 \frac{2}{5} m r_0^2 A^{5/3}$, where, $B_1 = \frac{1}{2}(r_1^2 + r_2^2)$, $r_1 = R_x/R_0 = \exp \left( \sqrt{5/4\pi} \right) \beta \cos (\gamma - 2\pi/3)$ and, $r_2 = R_y/R_0 = \exp \left( \sqrt{5/4\pi} \right) \beta \cos (\gamma + 2\pi/3)$. $R_x$, $R_y$ are the deformed radius parameters along the directions perpendicular to the spin axis and $R_0$ is that for an equivalent undeformed spherical shape. We have considered rotation axis along $z$, different from the

common convention of $\omega$ as parallel to $x$, as it leads to simplification of many expressions and calculations. However, we have plotted $\gamma$ as ($\gamma - 120^\circ$) in Fig. 4 and Fig. 5 in order to represent the equilibrium deformation in the conventional way.

TABLE I: Extracted GDR parameters for $^{32}$S used for CASCADE calculations. $E_1, E_2, \Gamma_1, \Gamma_2, S_1, S_2$ are the resonance energies, widths and fractional strengths respectively for the two GDR components.

| $E_{proj}$ (MeV) | $E_1$ (MeV) | $\Gamma_1$ (MeV) | $S_1$ | $E_2$ (MeV) | $\Gamma_2$ (MeV) | $S_2$ | $\beta$ |
|-----------------|-------------|------------------|------|-------------|------------------|------|--------|
| 145             | 14.5        | 6.2              | 0.37 | 25.4        | 7.5              | 0.63 | 0.68   |
| 160             | 14.0        | 6.2              | 0.32 | 26.0        | 8.2              | 0.68 | 0.76   |

The free energy surfaces were obtained for different spins over the entire $\beta$-$\gamma$ space as shown in Fig. 4 for $^{47}$V compound nucleus. It can be clearly seen that as the spin increases, the minima of the free energy surfaces move towards increasing oblate deformation (along y-axis) and suddenly make a transition towards the prolate ($\gamma=0^\circ$) deformation (represented by the line) at high spins. The gradual evolution in shape and the transition point are evident in a polar $\beta$-vs-$\gamma$ plot for discrete spins (Fig. 5). It is clear from the figure that
FIG. 5: (color online) The equilibrium shapes are plotted as a function of quadrupole deformation parameters $\beta$ and $\gamma$ for different spins for $^{47}$V and $^{32}$S nuclei. The discrete spin values are represented alongside the data points.

for $^{47}$V, with the increase in angular velocity, the nucleus becomes more and more oblate deformed ($\gamma=60^\circ$). After a critical spin of $27\hbar$ it suddenly becomes triaxial ($60^\circ < \gamma < 0^\circ$) and approaches a prolate shape at still higher spins.

Experimentally, the average angular momentum was deduced from a selection of the fold distribution of the low energy $\gamma$- multiplicity filter array [24] and corresponding to the $\langle J \rangle$ values the equilibrium shape of the nucleus is known (Fig. 5). The GDR observables ($E_{GDR}$, $\Gamma_{GDR}$) are calculated built on these shapes using Hill-Wheeler parametrization and considering $\Gamma_{GDR}^i = \Gamma_0 (E_{GDR}^i/E_0)^{\delta}$ [33], where, $\Gamma_0$ is the ground state GDR width and $\delta$ is taken as 1.9. This procedure in general gives three different GDR frequencies (along the three unequal axes) and widths corresponding to a particular angular momentum and equilibrium shape of the nucleus. These three GDR frequencies further split (the ones perpendicular to the spin axis) due to coriolis effect as the GDR vibrations in a nucleus couple with its rotation when viewed from a non-rotating frame [34]. The magnitude of the split depends on the magnitude of the rotation frequency and give rise to five GDR components. The resultant GDR lineshape is obtained as a superposition all the components $(E_i, \Gamma_i)$,

$$\sigma_{\text{total}} = \sum_{i=1}^{5} \frac{E_i^2 \Gamma_i}{(E_i^2 - E_i^2)^2 + E_i^2 \Gamma_i^2}$$

The TSFM assumes that at high $T$ and $J$, the GDR vibration samples an ensemble of different shapes around the equilibrium shape of the compound nucleus. Thus, the GDR lineshapes are generated (according to the adiabatic TSFM [35]) by averaging the GDR vibrations over the free energy surfaces (using a Boltzman probability distribution $\exp(-F/T)$).
in the entire deformation space including full orientation fluctuation using,

\[
\langle \sigma \rangle = \frac{\int D_\alpha e^{-F/T(\omega.I.\omega)}^{-3/2}\sigma}{\int D_\alpha e^{-F/T(\omega.I.\omega)}^{-3/2}}
\]

where, \( D_\alpha = \beta^4 \sin(3\gamma) d\beta d\gamma d\Omega \) is the elemental volume.

The resultant lineshape is compared with the experimental data and is plotted in Fig.3 (solid line). It describes the data for \(^{47}\text{V}\) remarkably well for both the experimentally measured spin windows of \(28h\) & \(31h\) (spin uncertainties of \(\pm 7h\) & \(\pm 8h\) respectively) at corresponding temperatures of \(2.9\) & \(2.8\) MeV respectively. The presence of the enhancement in the lineshape at \(\sim 10\) MeV and the goodness of description are characteristic signatures of Jacobi transition in the case of \(^{47}\text{V}\) nucleus at these spin values.

| \(E_{\text{proj}}\) (MeV) | \(< J > = 28h\) | \(< J > = 31h\) |
|-------------------------|------------------|------------------|
|                         | \(E_i\) | \(\Gamma_i\) | \(S_i\) | \(\beta\) | \(E_i\) | \(\Gamma_i\) | \(S_i\) | \(\beta\) |
| 9.9                     | 3.0   | 0.33            |
| 14.5                    | 5.3   | 0.15            |
| 18.3                    | 8.1   | 0.17            | 0.43      |
| 23.1                    | 11.3  | 0.17            |
| 27.3                    | 15.5  | 0.18            |

Since it is difficult to extract the angular momentum for very low mass accurately, the \(^{32}\text{S}\) nucleus was populated with two incident energies, 145 and 160 MeV, in order to populate \(^{32}\text{S}\) at different spins. The high fold gated spectrum of \(^{32}\text{S}\) for both the energies is shown in Fig.3. The similar free energy calculations are done at both low and high spins, but it fails miserably to describe the experimental data. The calculation performed at \(22h\) is shown in Fig.3 (dotted line (e),(f)). Though the nucleus is populated well above the critical spin for Jacobi transition (Fig.5), it does not show the characteristic behaviour of such a transition in shape. Instead, the data is reproduced quite well by a statistical model (CASCADE) calculation with a 2-component GDR strength function (tableI). The shapes suggest a strongly prolate deformed nucleus (\(\beta \approx 0.76\) for \(E_{\text{proj}}=160\) MeV, corresponding
to an axis ratio of 1.7:1). The $^{20}$Ne + $^{12}$C system was studied earlier at 5 MeV/u and 9.5 MeV/u to study the isospin effects in light mass nuclei [36] but only preliminary result was presented for the higher incident energy indicating towards incomplete fusion. Indeed, the pre-equilibrium component at 200 MeV incident energy, as measured from our earlier charge particle experiment, is around 50 %. However, the pre-equilibrium component in our case, less than 10% for 160 MeV and negligible at 145 MeV, does not seem to have a major influence on the high energy $\gamma$-spectra.

The occurrence of such a large deformation without showing the characteristics of Jacobi transition is possible only if some other reaction mechanism is responsible. One of the possibilities could be the formation of an orbiting di-nuclear complex where the nucleus is not fully equilibrated (in terms of shape degrees of freedom) and maintains the entrance channel shape before finally splitting into two parts. Our charged particle studies have also indicated a highly deformed orbiting dinuclear shape of this system. However, it can also be conjectured that the observed unusual deformation can be due to the formation of molecular structure of $^{16}$O + $^{16}$O cluster in $^{32}$S. In the theoretical work of Kimura and Horiuchi [37], it was predicted that the SD states of $^{32}$S have considerable amount of $^{16}$O + $^{16}$O components and become more prominent as the excitation energy increases. The extracted deformation for two touching $^{16}$O was found to be $\beta$=0.73 which is in agreement with the experimentally extracted deformation from the resonance energy peaks. The occurrence of GDR in nuclei, where the entire nucleus takes part in a collective manner, is clearly an effect of the mean field structure of the nucleus. It is also known that other inherent structures (molecular resonance and/or orbiting di-nuclear complex) in light $\alpha$-cluster nuclei may coexist with the mean field description of the nucleus. Whether the experimental signatures of the overall nuclear deformation via GDR $\gamma$-decay is due to the coexistence of these effects needs to be investigated further and are beyond the scope of this present study.

In summary, we have populated the nuclei $^{47}$V and $^{32}$S at the highest spins and high excitations and studied their shapes directly by looking at the lineshapes of their GDR decay. Both the nuclei show highly deformed structures corresponding to highly fragmented GDR strength functions. The $^{47}$V nucleus shows Jacobi triaxial shapes well beyond the critical transition point. The evolution of the nucleus as a function of angular momenta is estimated in the RLDM & TSFM framework and found to match exactly with the experiment. In the case of alpha cluster $^{32}$S nucleus, a highly deformed extended prolate configuration is evident
which does not follow the usual evolution of shape with angular momentum. This unusual deformation, seen directly for the first time, can be speculated due to the formation of either orbiting di-nuclear configuration or molecular structure of $^{16}\text{O} + ^{16}\text{O}$ in $^{32}\text{S}$ SD band.
