Sir,

Chronic obstructive pulmonary disease (COPD) is a chronic disease which predisposes to the appearance of opportunistic infections. Long-term corticosteroids therapy might favor this immunosuppression status. Next, we report a case of a COPD patient with a non-responding pneumonia, in which immunosuppression was potentiated by previous corticosteroid treatments and mucociliary clearance alteration.

A 75-year-old caucasian male, ex-smoker, with a medical history significant for type I obesity and severe COPD disease treated with triple bronchodilator therapy, presented at Emergency Department (ED) with dyspnea, cough and expectation from 1 week. A blood sample analysis revealed high acute-phase reactants (leucocytosis [21,900 cells/µL], neutrophilia [21,150 cells/µL], and high C-reactive protein (CRP) [173.6 mg/L]), with normal kidney function and haemostasis. Chest-X-ray showed moderate hypoxemia despite supplemental oxygen therapy (FiO2 0.35). Hence, he was hospitalized for ED medical treatment, the patient improved and was discharged with oral treatment (cefditoren and prednisone).

At home, the patient was clinically worsening and two months later he presented again at ED with pleuritic chest pain, dyspnea and tachypnoea (respiratory rate: 30 breaths per minute). New complementary explorations were completed: Blood analysis revealed high acute-phase reactants (leucocytosis [22,430 cells/µL], neutrophilia [18,810 cells/µL], high CRP [91.6 mg/L]) and a right lower lobe consolidation with ipsilateral pleural effusion was shown in chest-X-ray (Figure 1). A bronchoscopy was performed and it revealed abundant mucopurulent secretions. A bronchoalveolar lavage (BAL) was obtained from lingula.

The BAL microbiological tests showed negative results for respiratory viruses, fungi culture, galactomannan antigen and mycobacterial tests (Ziehl-Neelsen stain and Lowenstein culture). As considered a treatment failure, antimicrobial coverage was broadened (piperaclillin/tazobactam and oral voriconazole) and a CT-scan and a bronchoscopy were requested for obtaining invasive samples.

The CT-scan showed bilateral pulmonary nodules, with many lobes involved, heterogeneous in size (4-36mm) with hypodense regions of probable necrosis. The right basal consolidation has progressed and the pleural effusion persisted (Figure 2). A bronchoscopy was performed and it revealed abundant mucopurulent secretions. A bronchoalveolar lavage (BAL) was obtained from lingula.

The BAL microbiological tests showed negative results for Legionella, Mycobacterium and Mycoplasma. Nocardia cyriacigeorgica was isolated on Lowenstein culture. The patient was started on intravenous cotrimoxazole and imipenem. Because of the moderate-grade pulmonary nocardiosis, intravenous cotrimoxazole was started (sensitivity was confirmed). The patient showed clinical improvement, then intravenous antibiotic therapy was switched to oral cotrimoxazole. After 6 months of treatment, chest X-ray showed disappearance of consolidation, the patient was asymptomatic with no adverse reactions to treatment and treatment was discontinued.

Pulmonary nocardiosis (PN) is an opportunistic infection that belongs to Actinomycetaceae family and mainly affects immunocompromised patients. However, in one third of cases it can occur in immunocompetent patients. Nocardiidae spp. are Gram-positive, aerobic, filamentous, and partially acid-fast bacilli. PN has a high mortality rate up to 38% according to some case series [1].

Nocardiosis incidence is increasing due to the greater longevity of population, which has a senescent immune system [2] and higher number of chronic advanced comorbidities. Local alteration of the pulmonary defences predisposes to PN, as it occurs in COPD or lung sequestration [3,4].

Direct inoculation or inhalation of spores are the main transmission mechanisms of Nocardia. They may be found in sand, dust or in stagnant water [3].

Lung involvement is the main affection of Nocardia. However, disseminated involvement may occur in some cases (≥2 sites involvement in 32% of patients, according to case series). Disseminated disease involves central nervous system, bacteraemia and cutaneous or soft tissue infections [5].

Differential diagnosis of PN should be made with other infectious and non-infectious diseases, such as pneumocystis pneumonia, tuberculosis, fungal infections or ANCA-mediated vasculitis [2].

Gold standard for the identification of PN is the culture of Nocardia. Nocardia is a slow-growing bacterium that requires specific stains (Kiyoun or fluorescent auramine-rhodamine) and special cultures (modified Thayer Martin agar or BCYE-alpha agar). In other non-selective media, such as media for Mycobacteria, it can also grow (Löwenstein-Jensen) [5]. Molecular identification methods, such as Polymerase Chain Reaction (PCR) base sequencing, provide rapid results. However, these techniques are not available in all microbiology laboratories [2].

In immunosuppressed patients, a positive sputum culture leads to diagnosis of the disease and not only colonization [3]. In 44% of lung infections, invasive diagnostic procedures for obtaining lower respiratory samples may be necessary [6].

Decontamination methods (sodium hydroxide, benzalkonium chloride and N-acetyl-L-cysteine) are toxic for Nocardia [2] therefore, it is essential to inform to the microbiology laboratory if there is clinical suspicion.

Standard treatment for local PN is cotrimoxazole. Initially, intravenous administration is recommended. If clinical improvement is achieved, an oral administration could be considered. The treatment total duration is 6 months, although it must be extended to 12 months in immunosuppressed patients or in disseminated disease. In severe lung diseases or immunosuppression, combined treatment (cotrimoxazole + amikacin or imipenem + amikacin) is recommended. In associated central nervous system involvement, triple therapy with cotrimoxazole + imipenem + amikacin is recommended [7].
In conclusion, PN should be considered in immunosuppressed patients and, also in patients with other associated risk factors. Clinical suspicion is very important because specific microbiological tests are required. Nocardiosis requires prolonged and sometimes combined treatment.
