Abstract

We use the Panoramic Survey Telescope and Rapid Response System 1 Survey (Pan-STARRS1, PS1) data to extend the Sloan Digital Sky Survey (SDSS) Stripe 82 quasar light curves. Combining PS1 and SDSS light curves provides a 15 yr baseline for 9248 quasars—5 yr longer than prior studies that used only SDSS. We fit the light curves with the damped random walk (DRW) model—a statistical description of their variability. We correlate the resulting DRW model parameters: asymptotic variability amplitude $S_{\infty}$, and characteristic timescale $\tau$, with quasar physical properties—black hole mass, bolometric luminosity, and redshift. Using simulated light curves, we find that a longer baseline allows us to better constrain the DRW parameters. After adding PS1 data, the variability amplitude is a stronger function of the black hole mass and has a weaker dependence on quasar luminosity. In addition, the characteristic timescale $\tau$ dependence on quasar luminosity is marginally weaker. We also make predictions for the fidelity of DRW model parameter retrieval when light curves will be further extended with Zwicky Transient Facility and Rubin Observatory Legacy Survey of Space and Time data. Finally, we show how updated DRW parameters offer an independent method of discovering changing-look quasar candidates (CLQSOs). The candidates are outliers in terms of differences in magnitude and scatter between the SDSS and PS1 segments. We identify 40 objects (35 newly reported) with a tenfold increase in the variability timescale between SDSS and SDSS–PS1 data due to a large change in brightness (over 0.5 mag)—characteristic for CLQSOs.

Unified Astronomy Thesaurus concepts: Quasars (1319); Active galactic nuclei (16); Light curves (918)

1. Introduction

Quasars are variable at rest-frame optical wavelengths at an asymptotic rms level of about 0.2 mag. These distant galaxies harbor an actively accreting supermassive black hole: an active galactic nucleus (AGN). Although it is agreed upon that the majority of optical light originates from the thermal emission of the accretion disk, the detailed origin of variability has been debated for the past 50 yr (see Edelson et al. 2018 and references therein). Some favor a thermal origin of variability (Kelly et al. 2013) related to the propagation of inhomogeneities (“hot spots”) in the disk (Dexter & Agol 2011; Cai et al. 2016); others suggest magnetically elevated disks (Dexter & Begelman 2019) or X-ray reprocessing (Kubota & Done 2018). Indeed, it may well be that the answer involves a combination of these; as Sánchez-Sáez et al. (2018) suggested, perhaps short-term variability (hours to days) is linked to the changes in X-ray flux, while long-term variability (months to years) is more intrinsic to the disk (Edelson et al. 2015; Lira et al. 2015). Nevertheless, quasar optical light curves have been successfully described using the damped random walk (DRW) model (Kelly et al. 2009; Kozłowski et al. 2010; MacLeod et al. 2010; Zu et al. 2011; Kasliwal et al. 2015), and the DRW parameters have been linked to the physical quasar properties (MacLeod et al. 2010, hereafter M10).

Variability is also a classification tool, allowing one to distinguish quasars from other variable sources that do not exhibit a stochastic variability pattern (MacLeod et al. 2011). This property is especially useful for selecting quasars in the intermediate-redshift range, which overlaps the stellar locus in color–color diagrams (Sesar et al. 2007; Yang et al. 2017). Variability has also been used to increase the completeness in measurements of quasar luminosity function (see McGreer et al. 2013, 2018; Palanque-Delabrouille et al. 2013; Ross et al. 2013; AlSayyad 2016).

Power spectral density (PSD) informs us about the distribution of variability across the frequency range, from short timescales (high frequencies) to long timescales (low frequencies). Quasar—or, more broadly speaking, AGN—variability exhibits a broken power-law PSD of the form

$$P(f) \propto \alpha \log(f),$$

with $\alpha_{l}$ at low frequencies and $\alpha_{h}$ at high frequencies. For a pure DRW process, $\alpha_{h} = -2$ and $\alpha_{l} = 0$, so that

$$P(f) = \frac{4\sigma^{2}\tau}{1 + (2\pi\tau f)^{2}}$$

(with $\sigma = S_{\infty}/\sqrt{2}$, $\tau$ the characteristic timescale, and $f$ the frequency), where $P(f) \propto f^{-2}$ at high frequencies $f > (2\pi\tau)^{-1}$ and levels to a constant value at lower frequencies (Kelly et al. 2014).

There is a debate in the literature about the exact shape of the quasar PSD and any possible departures from the pure DRW model. Studies using quasar data from wide-field photometric surveys (OGLE, SDSS, PS1) benefit from relatively long baselines (several years), which constrain the low-frequency part of the PSD. Overall, there is no evidence of a significant departure from DRW at these long timescales, i.e., $\alpha_{l} \approx 0$ (Zu et al. 2013; Simm et al. 2016; Kozłowski 2016; Caplar et al. 2017; Guo et al. 2017; Sun et al. 2018). However, these ground-based surveys suffer from sparse sampling, which can be remedied by using a space-based telescope that can carry out near-continuous observations, like the Kepler mission (Borucki et al. 2010). Studies using Kepler data that focused on a smaller number of well-sampled AGNs with short baselines (<100 days) found a range of power-law slopes at high frequencies—from $-1$ to $-3.2$, which includes the DRW $\alpha_{h} \approx -2$—but further study is needed (Mushotzky et al. 2011; Edelson et al. 2014;
Aranzana et al. 2018; Smith et al. 2018). However, in this paper, the timescales probed are larger than several days; thus, we can assume that DRW is the best working description of quasar variability for available optical light curves. Furthermore, in this work, we directly compare the results of Sloan Digital Sky Survey (SDSS) light curves extended with the Panoramic Survey Telescope and Rapid Response System 1 Survey (Pan-STARRS1, PS1) to M10, who used pure DRW description (see discussion therein on a possible departure from DRW). Therefore, to allow a better comparison of our results with M10, we use the DRW description of quasar PSD.

Due to its stochastic nature, for an unbiased parameter retrieval of the DRW process, the light curve is required to be several times longer than the characteristic timescale (Kozłowski et al. 2010; Kozłowski 2017a, hereafter K17). This means that DRW parameters recovered for short light curves (compared to the recovered timescale) may be biased, which in turn affects the correlations with physical parameters (black hole mass, Eddington ratio, absolute luminosity).

For this reason, while some studies have restricted the probed redshift range, limiting the quasar sample to where one would expect only shorter timescales based on previous studies (Kelly et al. 2013; Simm et al. 2016; Guo et al. 2017; Sun et al. 2018), some have elected not to study timescales at all (Sun et al. 2018; Sánchez-Sáez et al. 2018) or to use the timescales recovered from short light curves primarily for classification (Hernitschek et al. 2016).

By extending the available quasar light curves, we are able to better recover DRW timescales. Since almost a decade ago, when M10 published their study based on SDSS Stripe 82 (S82) data, new data sets (PS1, PTF, CRTS) have become available. They can extend the quasar light curves by almost 50%. For instance, Li et al. (2018) combined SDSS and Dark Energy Camera Legacy Survey (DECaLS) data to provide a 15 yr baseline. However, using all SDSS quasars, rather than only those confined to a well-observed S82 equatorial region, meant that the majority of light curves suffered from a poor sampling (only a few epochs). Therefore, rather than directly fitting individual light curves, they had to resort to an ensemble structure function (SF) approach.

Unlike previous studies, in this work, by combining SDSS and PS1 data for the well-observed S82, we afford an extended baseline (15 yr), a large number (9000) of quasars, and a good cadence ($N > 60$ epochs), to which we fit the DRW model. The layout of this paper is as follows. We confirm in Section 2 that extending the quasar baseline is an important improvement in providing unbiased estimates of the DRW model parameters (K17); in Section 3, we describe the data sets employed and their combination into a common photometric system; in Section 4, we simulate the improvement in the recovery of DRW parameters with baseline extension and realistic cadence; in Section 5, we describe the main results, analyzing correlations between physical parameters and variability; in Section 6, we discuss the physical meaning of relevant timescales; and in Section 7, we summarize the main conclusions. In this work, we adopt a $\Lambda$CDM cosmology with $h_0 = 0.7$ and $\Omega_m = 0.3$.

2. Methods

2.1. DRW as a GP

The DRW (Ornstein–Uhlenbeck process; Rasmussen & Williams 2006) can be modeled as a member of a class of Gaussian processes (GPs). Each GP is described by a mean and a kernel: a covariance function that contains a measure of correlation between two points, $x_n$ and $x_m$, separated by $\Delta t_{nm}$ (autocorrelation). For the DRW process, the covariance between two observations spaced by $\Delta t_{nm}$ is

$$k(\Delta t_{nm}) = \sigma^2 \exp(-\Delta t_{nm}/\tau) = \sigma^2 \text{ACF} (\Delta t_{nm}).$$

(2)

Here $\sigma^2$ is an amplitude of correlation decay as a function of $\Delta t_{nm}$, while $\tau$ is the characteristic timescale over which correlation drops by $1/e$. For a DRW, the correlation function $k(\Delta t_{nm})$ is also related to the autocorrelation function.

Not explicitly used in this paper, but of direct relevance to the DRW modeling, is the SF. It can be found from the data as the rms scatter of magnitude differences $\Delta m$ calculated as a function of temporal separation $\Delta t$ (we drop the subscripts $n$ and $m$ for brevity). The SF is directly related to a DRW kernel $k(\Delta t)$:

$$\text{SF}(\Delta t) = \text{SF}_\infty(1 - \exp( - |\Delta t| / \tau ))^{1/2}.$$  

(3)

For quasars, SF approximately follows a power law, $\text{SF} \propto \Delta t^{-\beta}$, and for large time separation $\Delta t$, as epochs in the light curve cease to be correlated, it levels out to a constant value $\text{SF}_\infty$: the asymptotic SF. Note that $\sigma$ in Equation (2) is related to the asymptotic SF as $\text{SF}_\infty = \sqrt{2} \sigma$ (also see Bauer et al. 2009; MacLeod et al. 2012; Graham et al. 2015 for an overview).

2.2. Fitting

We evaluate the likelihood of the DRW model with a particular set of $\tau$, $\sigma$ given the data with celerite, a fast GP solver (Foreman-Mackey et al. 2017). The underlying matrix algebra is similar to that used by Rybicki & Press (1992), Kozłowski et al. (2010), and M10. Also, as in previous work, we use a prior on the DRW parameters that is uniform in log space: $1/(\sigma \tau)$. The main difference in our approach is that rather than adopting the maximum a posteriori (MAP) as the “best-fit” value for the DRW parameters (as in Kozłowski et al. 2010, K17; Kozłowski 2016, M10; MacLeod et al. 2011), we find the expectation value of the marginalized posterior. This is advantageous because of the non-Gaussian shape of the posterior; otherwise, if the posterior was a 2D normal distribution, the expectation value would coincide with the maximum of the posterior (MAP solution).

2.3. The Impact of the Light-curve Baseline

It was reported by K17 that one cannot trust any results of DRW fitting unless the light curve is at least 10 times longer than the characteristic timescale. In this section, we revisit the relationship between recovered and input timescales as a function of light-curve baseline by following the K17 setup. We confirm that the bias in retrieved DRW timescale depends on how many times the light curve is longer than the timescale. However, we find that the baseline does not have to be as many as 10 times longer to provide meaningful, rather than unconstrained, results. Assuming a fixed baseline of $\Delta T = 8$ yr, we simulate 10,000 light curves, exploring 100 values of input timescales but identical $\text{SF}_\infty = 0.2$ mag with either SDSS ($N = 60$) or OGLe-like ($N = 445$) cadence. Defining $\rho$ as the ratio of input timescale to baseline, we probe a range of $\rho$ between 0.01 and 15, uniform in a logarithmic grid.
For each light curve, we simulate the underlying DRW signal \( s(t) \) by iterating over the array of time steps \( t \). At each step, we draw a point from a Gaussian distribution, for which the mean and standard deviation are recalculated at each time step (see Equations A4 and A5 in Kelly et al. 2009; Section 2.2 in M10; K17). Initially, at \( t_0 \), the signal is equal to the mean magnitude, \( s_0 = \langle m \rangle \). After a time step \( \Delta t = t_{i+1} - t_i \), the signal \( s_{i+1} \) is drawn from a normal distribution \( \mathcal{N}(loc, stdev) \), with

\[
loc = s_i e^{-r} + \langle m \rangle (1 - e^{-r})
\]

and

\[
stdev^2 = 0.5 SF^2(1 - e^{-2r}),
\]

where \( r = \Delta t / \tau \), and \( \tau \) is the damping timescale. Like K17, we add to the true underlying signal with zero mean \( s(t) \) and a mean magnitude \( (r_{SDSS} = 17 \text{ mag} \) and \( l_{OGLE} = 18 \text{ mag} \) and calculate a magnitude-dependent estimate of photometric uncertainty:

\[
\sigma_{SDSS}^2 = 0.013^2 + \exp[2(r_{SDSS} - 23.36)],
\]

\[
\sigma_{OGLE}^2 = 0.004^2 + \exp[1.63(l_{OGLE} - 22.55)].
\]

To simulate observational conditions, we add the Gaussian noise \( n(t) = \mathcal{N}(0, \sigma(t)) \):

\[
y(t) = s(t) + n(t).
\]

The resulting distribution of fitted timescales as a function of input timescales scaled by the 8 yr baseline, \( \rho_{out} \) versus \( \rho_{in} \), is shown in Figure 1. We confirm the findings of K17: for short light curves, the best-fit \( \tau \) becomes \( \sim 1/5 \) of the light-curve length (where \( \log_{10}(\rho_{out}) \approx -0.7 \), the “unconstrained” region; bottom left in each panel). However, as long as the light curve is several times longer than the timescale \( (1/\rho \gtrsim 3 \text{, i.e., } \log_{10}(\rho) \lesssim 0.5) \), we can recover the timescale without substantial bias (the dashed line approaches the solid diagonal line in both panels). In summary, in this section, we showed that when using a DRW description for quasar light curves, extension of the light-curve baseline moves the fit results from the biased region (Figure 1, bottom left of each panel) to the unbiased regime (Figure 1, top right of each panel). This is the basis for this study, in which we extend the baselines of quasar light curves from SDSS only (10 yr) to combined SDSS–PS1 (15 yr).

3. Data

We focus on the data pertaining to a 290 deg\(^2\) region of the southern sky known as S82, repeatedly observed by the SDSS between 1998 and 2008. Originally aimed at supernova discovery, objects in this area were reobserved 60 times, on average (see MacLeod et al. 2012, Section 2, for overview and Annis et al. 2014 for details). Availability of well-calibrated (Ivezić et al. 2007), long-baseline light curves spurred variability research (Sesar et al. 2007). The DR9 catalog (Schneider et al. 2008) contains 9258 spectroscopically confirmed quasars within S82. Using a 0.5 matching radius, we find corresponding data for 9248 quasars from the PS1 DR2 (Chambers et al. 2016; Flewelling 2018; Flewelling et al. 2020), 7737 from the Catalina Real-Time Transit Survey (CRTS; Drake et al. 2009), 6455 from the Palomar Transient Factory (PTF; Rau et al. 2009), and 8001 from the Zwicky Transient Facility (ZTF) DR1 (Bellm et al. 2019; Masci et al. 2019). In this section, we first consider the possibility of utilizing data from all surveys and the challenges involved in combining the data from varying filter sets. We conclude that, with its shallower photometry (Figure 2) and baseline overlapping with SDSS–PS1, the added data from the CRTS would be compromised by its large photometric uncertainty (Figure 3) and the necessity of converting from a broad CRTS V-band filter (white light) to SDSS r. Similarly, the ZTF and PTF were deemed too shallow for optimal data combination (median 0.1 mag uncertainty, as opposed to 0.02 mag for SDSS and 0.03 mag for PS1; see Figure 3). Finally, utilizing photometric offsets, although considered and calculated (Figure 4), would complicate the investigation into quasar variability by adding an additional layer of uncertainty, and for this reason, we use only SDSS and PS1 r-band data, as these bandpasses are sufficiently similar that no offset is required (see Figure 5).

Figure 2 illustrates the improvement in baseline coverage when combining various surveys. The length of each thick dashed line
corresponds to the duration of each survey (survey baseline), and the size of each circle corresponds to the area covered by each survey. The vertical location of each dashed line marks the $5\sigma$ depth in the $r$ band (or equivalent). The Rubin Observatory Legacy Survey of Space and Time (LSST) stands out in that it will provide the best extension of SDSS baseline and depth.
Combining data from different photometric standards requires applying color transformation or photometric offsets. We first seek to combine PS1 gri, PTF gR, and CRTS r into a common SDSS r band (best photometry). To this end, we calculate color terms using the SDSS standard star catalog (Ivezić et al. 2007). Focusing on 100,000 randomly chosen stars, we find their CRTS, PS1, and PTF matches.

The difference between the target (SDSS) and source (e.g., PS1) photometry can be written as a function of the mean SDSS g – i color:

$$m_{\text{PS1}} - m_{\text{SDSS}} = f(g - i).$$  (9)

Some authors (e.g., Li et al. 2018) allow the transformation to be a higher-order polynomial, but as Figure 6 shows, quasars occupy a relatively narrow region of g – i color space, and we find that the linear fit is sufficient. The derived linear coefficients for photometric transformations between SDSS r and PS1 g, PTF gR, and CRTS r as a function of SDSS g – i color are listed in Table 1. We illustrate the process, showing in Figure 4, the SDSS–PS1 standard star data used to calculate the offsets. Note that the PS1 r (middle panel) is very close to the SDSS r, within 0.01 mag (1% level) across the g – i color range. We focus on the SDSS r–PS1 r offset as a function of magnitude in Figure 5; the near-equivalence of bandpass coverage is valid at the 1% level up to r < 20.5.

In selecting the most beneficial data sets to complement SDSS r, we also consider the associated photometric uncertainties (aka “errors”). As shown in Figure 2, PTF and CRTS are shallower than SDSS or PS1 (∼20.5 mag versus 22 mag). Therefore, for faint objects like quasars (for the S82 sample, the population median is SDSS r ∼ 20 mag), PTF and CRTS have larger photometric uncertainties than SDSS or PS1. Indeed, as Figure 3 shows, the distribution of median errors for PTF, CRTS, and ZTF quasar data (median ∼0.1–0.15 mag) is wider than the corresponding SDSS and PS1 data (median ∼0.02–0.04 mag). As simulations show (Section 4), although PTF and CRTS data do extend the SDSS baseline, their error properties decrease their utility in complementing the SDSS data set. After all, the SDSS baseline extension afforded with PTF and CRTS is comparable to that achieved with PS1 data alone (Figure 2).

Furthermore, to mitigate problems that could arise when applying photometric transformations (such as spurious variability due to incorrect offsets or color-dependent variability), we choose to combine SDSS r with only PS1 r, since, as Figures 4 and 5 show, SDSS r and PS1 r are sufficiently similar (at a 1% level up to 20.5 mag) that no photometric transformation is required.

Finally, we clean the combined SDSS r–PS1 r quasar light curves using standard procedures of σ-clipping in magnitude and error space and error-weighted day averaging to mitigate the impact of bad photometry and average out the intranight variability (as in Charisi et al. 2016; Suberlak et al. 2017). Of 9248 SDSS–PS1 quasars, 8516 have PS1 r data with 662,092 epochs. We remove points that have errors departing from the median SDSS(PS1) light-curve segment by more than 7σ, and we visually inspect all photometry with magnitudes departing by more than 7σ from the median magnitude. Of 585 flagged light curves, 253 required removal of individual epochs containing bad photometry. To avoid unphysically small errors, we add in quadrature 0.01 mag if the combined nightly error is <0.02 mag. In the final sample, there are 580,321 epochs.

In conclusion, we use SDSS S82 data spanning 10 yr in the observed frame extended by the PS1 DR2 data that add, on average, 5 yr of data. Although we considered utilizing ZTF, PTF, and CRTS data, their larger photometric uncertainties offset any gain due to the extended baseline. Furthermore, only the SDSS and PS1 r bands are sufficiently similar (at a <0.01 mag level; Figure 5) that no photometric offsets are required, which would unnecessarily complicate merging light curves from different surveys.

4. Simulations: Lessons Learned

We simulate the theoretical improvement of the DRW parameter retrieval in extended light curves. We generate long and well-sampled “master” light curves, all with input τ = 575 days, $S_{\text{F}} = 0.2$ mag (the median of S82 quasar distribution in M10), with zero mean. We subsample at real observed epochs for SDSS and PS1 and predicted cadences for ZTF and LSST (see Figure 7). To each simulated light curve, we add a magnitude offset corresponding to the mean of the combined SDSS–PS1 light curve. That way, the magnitude distribution of simulated light curves is similar to that of the observed SDSS–PS1 data. For the LSST 10 yr segment (finishing in 2031), we assumed 50 randomly distributed epochs per year, with the following error model:

$$\sigma_{\text{LSST}}(m)^2 = \sigma_{\text{sys}}^2 + \sigma_{\text{rand}}^2 (\text{mag})^2$$

$$\sigma_{\text{rand}}^2 = (0.04 - \gamma)x + \gamma x^2$$

$$x = 10^{0.4(m - m_\text{s})},$$  (10)

with $\sigma_{\text{sys}} = 0.005, \gamma = 0.039$, and $m_\text{s} = 24.7$ (see Ivezić et al. 2019, Section 3.2). For the ZTF 1 yr segment (spring 2019 ZTF DR1, including the data from 2018), we assumed 120 observations (every 3 nights) in g_{ZTF} and r_{ZTF}, deriving the magnitude-dependent error model by plotting the best mag rms as a function of the best median magnitude for ZTF matches to S82 standard stars in Figure 8. We find that the LSST error

---

5 CRTS from B. Sesar, private communication; PS1 from MAST (http://panstars.stsci.edu); and PTF from the IRSA PTF Object Catalog (https://irsa.ipac.caltech.edu/).
model (Equation (10)) with $\gamma = 0.05$, $\sigma_{\text{sys}} = 0.005$, and $m_S = 20.8$ adequately describes the ZTF photometric uncertainty.

To mirror observational conditions, we add a Gaussian noise to the true underlying DRW signal with variance defined by photometric uncertainties for corresponding surveys. Figure 7 illustrates the simulated “master” light curve (black dots; four day$^{-1}$) subsampled at SDSS (red), PS1 (green), and LSST (blue) cadence. While PS1 provides a 50% improvement of the SDSS baseline, LSST will nearly triple it. Figure 9 shows how the simulated distribution of DRW parameters $\sigma$, $\tau$ changes as the SDSS quasar light curves are extended with PS1, ZTF, and LSST data. We quantify the improvement in recovery of DRW parameters with an rms error calculated for $\sigma_{\text{in}}/\sigma_{\text{in}}$ and $\tau_{\text{in}}/\tau_{\text{in}}$. For ratio $r$, $\text{rms}(r)^2 = \text{bias}(r)^2 + \sigma_g(r)^2$. For $r = \sigma_{\text{in}}/\sigma_{\text{in}}$, the rms changes from 0.322 (SDSS only), to 0.273 (SDSS–PS1), to 0.305 (SDSS–PS1–ZTF), to 0.182 (SDSS–PS1–ZTF–LSST). In the future (after more data have been assembled and recalibrated), ZTF will help, but not as dramatically as LSST (which provides a factor of 1.8 improvement in rms errors in $\sigma_{\text{in}}/\sigma_{\text{in}}$ and a factor of 1.5 for $\tau_{\text{in}}/\tau_{\text{in}}$). Note that, due to larger errors (Figure 3), including ZTF causes a widening of the recovered $\tau$ distribution—the rms increases from 0.715 with SDSS to 0.890 with SDSS–PS1–ZTF (see Figure 9). Using PS1 data with their excellent deep photometry (as compared to ZTF or PTF) is the best improvement over existing SDSS results (factor of 1.2 decrease of rms errors for $\sigma$ and a smaller increase for rms errors for $\tau$; factor of 1.25 comparing SDSS–PS1–ZTF versus factor of 1.07 for SDSS–PS1). For this reason, we use only the SDSS–PS1 portion of quasar light curves as the best trade-off between adding more baseline versus introducing more uncertainty with noisy data.

In summary, to gauge the improvement in the recovery of DRW parameters due to extending quasar light curves, we simulate 8516 well-sampled light curves, subsampled at real cadence for SDSS and PS1 segments, and predicted cadences
Figure 7. Simulated well-sampled underlying DRW process, one of “master” light curves ($\tau = 575$ days, $\sigma_{\text{sys}} = 0.2$ mag, 4 points day$^{-1}$), shown with small black dots. To simulate observations, the cadence is degraded (subsampled) to match the ground-based cadence corresponding to real quasar data from SDSS (red), PS1 (green) segments, and simulated LSST (blue) epochs (here we use SDSS–PS1 epochs for quasar dbID = 3537034). The orange “error snake” is an envelope marking the standard deviation of the fit to the data using a GP with a DRW kernel (Section 4).

Figure 8. Best mag rms plotted as a function of magnitude for ZTF nonvariable stars with over 100 observations. We overplot the adopted error model, with $\gamma = 0.05$, $\sigma_{\text{sys}} = 0.005$, and $m_5 = 20.8$ (see Equation (10)). The properties of the ZTF photometric uncertainties are largely similar to the PTF uncertainties.

5. Results: Variability Parameters for S82 Quasars

We extend the S82 quasar light curves by combining the SDSS $r$-band data with the PS1 $r$-band data without any photometric offsets. For each quasar, we fit the SDSS and SDSS–PS1 segments with the DRW model. This yields two sets of DRW parameters per quasar: $(\tau_{\text{SDSS}}, \sigma_{\text{SDSS}})$ and $(\tau_{\text{SDSS–PS1}}, \sigma_{\text{SDSS–PS1}})$. Because variability is inherent to the quasar, for the remaining analysis, we shift all fitted timescales to the quasar rest frame and implicitly assume that the DRW timescales are considered in the rest frame: $\tau_{\text{RF}} = \tau_{\text{obs}}/(1 + z)$.

In this section, we first correct the fitted $\tau$, $\sigma$ for wavelength dependence. Then we show consistency with the M10 results and consider the trends between DRW parameters and physical quasar properties: black hole mass $M_{\text{BH}}$, absolute $i$-band magnitude $M_i$, or redshift $z$.

5.1. Comparison to M10

The DRW parameters recovered with celerite are broadly consistent with M10; Figure 10 shows the rest-frame $\tau$ and $\sigma_{\text{sys}}$ distributions for our results for the SDSS segment (blue dashed contours), SDSS–PS1 combined light curves (green dotted–dashed contours), and M10 SDSS for $r$-band only (red solid contours). When using exactly the same data as M10 (SDSS), our results agree. The offset of 0.05 dex between our results and those of M10 for SDSS, seen in the left panel of Figure 11, can be attributed to data cleaning and software differences. The right panel of Figure 11 shows the same distribution in terms of $K - \hat{\sigma}$ space, orthogonal to $\tau - \sigma$, where $\hat{\sigma} = \sqrt{2}/\tau$, and $K = \tau\sqrt{\sigma}/2^{1/4}$.

5.2. Outliers: Possible CLQSO Candidates

Figures 12 and 13 show the change in recovered DRW parameters between SDSS and combined SDSS–PS1 light curves. In Figure 12 the distribution of $f_r = \log_{10}(\sigma_{\text{SDSS–PS1}}/\sigma_{\text{SDSS}})$ and $f_r = \log_{10}(\sigma_{\text{SDSS–PS1}}/\sigma_{\text{SDSS}})$ for real light curves (left) matches the predicted distribution for simulated light curves (right). Analogously, in Figure 13 these ratios converted to a $K - \hat{\sigma}$ space also show close correspondence between the observed (left) and simulated (right) light curves. Studies show that about 0.1% of quasars will exhibit large variability (in excess of 0.5 mag rms; see Figure 18 in MacLeod et al. 2012). Visual inspection of light curves in the top right region of the left panel of Figure 12 (marked by the red rectangle) reveals large changes in brightness, similar to those seen in changing-look quasars (CLQSOs; Elitzur et al. 2014; LaMassa et al. 2015; Schawinski et al. 2015; Guo et al. 2016; Ruan et al. 2016; Runnoe et al. 2016; Blanchard et al. 2017; Gezari et al. 2017; Stern et al. 2017; Sheng et al. 2017; Lawrence 2018; Ross et al. 2018; Stern et al. 2018; Yang et al. 2018; Frederick et al. 2019; MacLeod et al. 2019;
Ruan et al. 2019; Trakhtenbrot et al. 2019; Shen et al. 2019; Sheng et al. 2020). The rectangle in Figure 12 marks the region with $f_r > 1$, $f_r > 0.4$. There are 28 objects in the simulated sample and 48 objects in the observed sample with that property, which reflects the fact that we do expect quasars to exhibit changes in their brightness as a function of time, with larger variance possible over longer timescales. We further select 40 of these that are brighter than 20.5 median PS1 r-band magnitude, since PS1 observations correspond to more recent epochs and provide a better indication of the possibility of follow-up. The light curves and properties of these CLQSO candidates are further discussed in Appendix B.

Such large differences in timescale and amplitude of variability can also be inferred directly from the light curves. Consider the difference in magnitude and scatter between the SDSS portion of the light curve (spanning approximately 10 yr between 1998 and 2008) and the PS1 portion (spanning ~5 yr between 2009 and 2014; see Figure 2). We measure the median magnitudes offset as $\Delta(\text{median}) = \text{median(SDSS)} - \text{median(PS1)}$ and the scatter difference as $\Delta(\sigma_G) = \sigma_G(\text{SDSS}) - \sigma_G(\text{PS1})$. The resulting distributions of $\Delta(\text{median})$ and $\Delta(\sigma_G)$ for S82 quasars are shown in Figure 14. Indeed, when plotting $\Delta(\text{median})$ as a function of $f_r$ and $f_r'$, there is a gradient indicating that the CLQSO candidates, outliers in $(f_r, f_r')$ space, are also outliers in $\Delta(\text{median})-\Delta(\sigma_G)$ space. Thus, the by-product of extending light curves to recalculate the DRW parameters with increased fidelity is an independent method to discover the CLQSO.

5.3. Rest-frame Wavelength Correction

Objects at cosmological distances are embedded in the Hubble flow due to the expansion of the universe (Riess et al. 2019). Therefore, light observed from a distant quasar would have been emitted at shorter wavelengths in the quasar’s rest frame, $\lambda_{\text{RF}} = \lambda_{\text{obs}}/(1 + z)$, where $z$ is the cosmological redshift. Quasars at different redshifts probe different regions of rest-frame spectra (see Figure 7 in Shen et al. 2019). Thus, before correlating the DRW parameters with quasar properties, we correct $\sigma$, $\tau$ for the $\lambda_{\text{RF}}$ dependence studied by M10 with SDSS $ugriz$ light curves. We plot the DRW parameters in Figure 15: $\sigma_{\infty}$ and $\tau$ as a function of $\lambda_{\text{RF}}$. A solid line marks the M10 best-fit power-law trend,

$$f \propto \left( \frac{\lambda_{\text{RF}}}{4000 \ \text{Å}} \right)^B,$$

with $B = -0.479$ and 0.17 for $\sigma_{\infty}$ and $\tau$, respectively.
5.4. Trends with Black Hole Mass, Absolute Luminosity

In the era of large synoptic surveys such as ZTF or LSST, the large increase in the number of discovered quasars means that due to limited observational resources, we can afford a spectroscopic follow-up for only a few percent of AGNs with optical time series (Ivezić et al. 2019). Therefore, a relationship between the quasar variability parameters ($\tau$, $\sigma$) and physical properties ($M_{\text{BH}}$, $M_i$) could provide an estimate of the latter for millions of quasars. We inspect correlations between $\tau$, $\sigma$ and $M_{\text{BH}}$, $M_i$ using the Shen et al. (2011) catalog, based on single-epoch SDSS spectra. Here $M_i$ is k-corrected to $z = 2$, corresponding to the peak of quasar activity (Richards et al. 2006). For details, see Appendix A.

In Figure 16, we examine the distribution of $M_{\text{BH}}$, $M_i$ as a function of $z$ for S82 quasars. The upward gradient in the top panels reflects the selection effect that higher-redshift quasars have to be brighter to be included in the magnitude-limited sample (luminosity–redshift degeneracy; see Section 5, Figure 12 in M10 and Dong et al. 2018). Higher-redshift quasars are also more active and have higher black hole masses due to cosmological downsizing (see McLure & Dunlop 2004;...
The distribution in the bottom left panel of Figure 16 is peaked at $z = 2$, which corresponds to the peak of quasar activity.

Figure 17 shows the DRW parameters for S82 quasars, $\tau$ and $S_{\infty}$, plotted as a function of quasar physical properties $M_{\text{BH}}$, $M_{i}$, and $z$. The left panels in Figure 17 contain a gradient of $S_{\infty}$ with $M_{i}$; brighter quasars have lower variability amplitude, largely independent of black hole mass.

We investigate these relations in more detail by fitting $f(\tau$ or $S_{\infty})$ as a power-law function of $M_{\text{BH}}$, $M_{i}$, and $z$,

$$\log_{10} f = A + B \log_{10}(\lambda_{RF}/4000 \, \text{Å}) + C(M_{i} + 23) + D \log_{10}(M_{\text{BH}}/10^{9}M_{\odot}).$$

(12)

using a Bayesian linear regression method that incorporates measurement uncertainties in all latent variables (Kelly 2007).
This ansatz is identical to that used by M10 and very similar to the relation used by Scaringi et al. (2015), since, for black holes, their Equation (1) becomes \( \log t_h = A' \log M_{\text{BH}} + B' \log L_{\text{Bol}} + C' \), where \( t_h \) is the PSD break timescale.

We compare the change in retrieved fit coefficients caused by adding PS1 data to SDSS against the M10 SDSS-only study. Note that M10 fitted a DRW model treating each of the five SDSS bands as a separate light curve, resulting in over 30,000 values of \( \tau, SF_\infty \) for 9000 S82 quasars. Grouping the fitted quasar parameters by band, they were correlated to the quasar physical parameters with Equation (12). Figure 18 shows the posterior samples for fitting Equation (12) to \( f = SF_\infty \) for quasar data separately for each SDSS bandpass. Each band yields a slightly different fit coefficient. As the fit result, M10 reported the band mean (red vertical dashed line). Since this study uses only \( r \)-band data, we compare the fit coefficients to M10 SDSS \( r \) data (green vertical solid line in Figure 18). We show the results of fitting Equation (12) to new SDSS and SDSS–PS1 parameters in Figures 19 and 20. First, with \( f = \tau \) in Equation (12) (Figure 19), the SDSS–PS1 data confirm M10 for luminosity dependence (the posterior Markov Chain Monte Carlo (MCMC) samples overlap), but the dependence of \( \tau \) on \( M_{\text{BH}} \) is marginally weaker (by 0.007 dex). Second, in Figure 20 with \( f = SF_\infty \), \( SF_\infty \) has a slightly weaker dependence on \( M_{\text{BH}} \) (by 0.04 dex compared to M10). The difference between the celerite SDSS-only results and M10 can be attributed to data cleaning that was not performed by M10 and

Figure 16. Distribution of quasars as a function of redshift, observed \( i \)-band magnitude, absolute \( i \)-band magnitude (\( k \)-corrected to \( z = 2 \)), and virial black hole mass. All data are from Shen et al. (2011).
software differences. Each distribution from Figures 19 and 20 is summarized in Table 2, with the uncertainty in the A, C, and D fit coefficients estimated from the standard deviation of the posterior samples.

We also searched for a signal of Mg II variability (see Cackett et al. 2015 for a review). Like Hα and Hβ, Mg II is a permitted low-ionization line (Yang et al. 2020), but on average, it is being emitted by gas further away from the ionizing source than the Hβ, possibly at the edge of the broad-line region (BLR; Guo et al. 2020). Ivezić et al. (2004) and MacLeod et al. (2012) studied the SDSS–POSS sample of quasars and reported the detection of a decrement in the difference between the data and the best-fit model (residuals) around 2800 Å when plotting the residuals as a function of Δτ and λRF. We investigate the residuals for f = SF∞ in Equation (12). We find that, using the SDSS data, the decrement in the median(τRF) around 2800 Å is visible at ~3σ relative to the smooth model, but by adding the PS1 data, the significance rises to ~5σ. We do not see much difference with regard to using the subset of 6371 quasars for which M10 had reliable results (listed in Table 2) versus the full set of 8516 quasars fitted with celerite for DRW parameters. The effect is interesting but does not produce a very significant signal; see Appendix C for more details.

Figure 17. Absolute i-band magnitude Mi (k-corrected to z = 2) as a function of the virial black hole mass MBH (bottom panels) and redshift z (top panels), colored by the long-term variability amplitude SF∞ (left panels) or characteristic timescale τ (right panels). Here Mi is a proxy for quasar bolometric luminosity, and the DRW variability parameters are for combined SDSS–PS1 r-band data.
Figure 18. Posterior MCMC draws for fitting Equation (12) with M10 variability amplitude $SF_{\infty}$ against $M_{BH}$, $M_i$, and $z$ (Shen et al. 2011). Since M10 treated the near-simultaneous SDSS ugriz data for 9258 quasars independently for each band, this resulted in DRW fit parameters for 7014 $u$, 7408 $g$, 6871 $r$, 6814 $i$, and 5111 $z$-band SDSS quasar light curves that fulfilled the M10 quality of DRW fit selection criteria. The M10 values for $SF_{\infty}$ are corrected to 4000 Å using Equation (11), with the power-law coefficient $B = -0.479$. Each distribution corresponds to a different SDSS band. We compare the results of fitting the SDSS–PS1 $r$ band directly against the M10 results for the SDSS $r$ band (green solid). Note that Table 1 in M10 reported band-averaged values for the A, C, and D coefficients (red vertical dashed line), while we cite in Table 2 the mean for the $r$ band (green vertical solid line).

Figure 19. Distribution of MCMC posterior draws fitting Equation (12) for the characteristic timescale ($f = \tau$) based on SDSS $r$-band results (dashed blue line) and new SDSS–PS1 combined $r$-band results (solid green line). These are considered simultaneously as a function of quasar absolute magnitude $M_i$ (left panel) and black hole mass $M_{BH}$ (right panel). Of 9258 spectroscopically confirmed quasars in S82, we employed 8516 that had PS1 matches, of which 6371 fulfill the M10 selection criteria (see M10, Section 2.2). The results from the SDSS–PS1 light curves are consistent with M10 for the SDSS $r$ band.

Figure 20. Same as Figure 19 but fitting the DRW asymptotic amplitude ($f = SF_{\infty}$ in Equation (12)) as a function of absolute magnitude $M_i$ and black hole mass $M_{BH}$. New data from PS1 are consistent with the earlier results of M10 on luminosity dependence but support a slightly weaker dependence of $SF_{\infty}$ on $M_{BH}$ (by 0.06 dex).
Figure 21. Absolute i-band magnitude $M_i$ as a function of black hole mass $M_{\text{BH}}$, where color encodes the Eddington ratio $f_{\text{Edd}} = L/\lambda_{\text{Edd}}$ (first panel), variability amplitude $\sigma_{\text{SF}}$ (second panel), or quasar count (third panel). We only plot bins with more than five quasars. The fourth panel shows the median $\sigma_{\text{SF}}$ as a function of the median $f_{\text{Edd}}$ (green crosses), averaged in bins of $f_{\text{Edd}}$ (open circles). The bin width $w$ is found to ensure an equal number of points (crosses) per bin (N). The error bars are $\sigma = 1.25\, \hat{\sigma}_{\text{bin}}/\sqrt{N}$, where $\hat{\sigma}_{\text{bin}}$ is the robust estimate of the standard deviation ($\hat{\sigma}_{\text{rob}} = 0.7413Q_{0.25} - Q_{0.75}$). We assume the uncertainty along $f_{\text{Edd}}$ as $\sigma_{\text{Edd}} = w/\sqrt{N}$ (see Ivezic et al. 2014). The solid orange line is the best-fit slope, $-0.207 \pm 0.031$, with the slope uncertainty estimated from the standard deviation of the posterior samples. The best-fit slope agrees with the M10 results ($-0.23 \pm 0.03$), plotted as a dashed magenta line.

Table 2

| $f$   | Source | $A$ (offset) | $B$ ($\lambda_{\text{Edd}}$) | $C$ ($M_i$) | $D$ ($M_{\text{BH}}$) |
|-------|--------|--------------|-------------------------------|-------------|-----------------------|
| $\tau$ | M10, SDSS | $2.5 \pm 0.027$  | $0.17 \pm 0.02$ | $0.03 \pm 0.009$ | $0.178 \pm 0.027$  |
|       | S20, SDSS | $2.515 \pm 0.019$ | $0.17 \pm 0.02$ | $0.042 \pm 0.007$ | $0.127 \pm 0.019$  |
| $\sigma_{\text{SF}}$ | S20, SDSS–PS1 | $2.597 \pm 0.02$ | $0.17 \pm 0.02$ | $0.035 \pm 0.007$ | $0.141 \pm 0.02$  |
| $\sigma_{\text{SF}}$ | S20, SDSS | $-0.486 \pm 0.012$ | $-0.479 \pm 0.005$ | $0.119 \pm 0.004$ | $0.121 \pm 0.012$  |
|       | S20, SDSS–PS1 | $-0.543 \pm 0.009$ | $-0.479 \pm 0.005$ | $0.125 \pm 0.003$ | $0.104 \pm 0.008$  |
| $\sigma_{\text{SF}}$ | S20, SDSS–PS1 | $-0.476 \pm 0.008$ | $-0.479 \pm 0.005$ | $0.118 \pm 0.003$ | $0.118 \pm 0.008$  |

Note. Here $B$ is fixed to $0.17$ or $-0.479$ from fitting a power law between $\lambda_{\text{Edd}}$ and $\tau$, $\sigma_{\text{SF}}$ (see Figure 15). Of 8516 quasars with SDSS–PS1 data, for consistency, here we use an unbiased subset of 6371 quasars for which M10 had reliable results. For $f = \tau$, $C$ is almost the same between M10 and this work for SDSS–PS1 (rows 1 and 3). However, $D$ based on SDSS–PS1 data is larger than M10 by 0.01 dex (row 3). For $f = \sigma_{\text{SF}}$, SDSS–PS1–based $C$ is within 0.01 dex of M10 (rows 4 and 6), and $D$ based on SDSS–PS1 data is almost identical to M10. When using celerite $\tau$ ($\sigma$) results for all 8516 quasars, the luminosity dependence is unchanged to within 0.01 dex, and the dependence on the black hole mass is stronger by 0.05 dex (0.02 dex), respectively. As shown in Figure 11, there is a small offset between $\log_{10}(\sigma_{\text{SF}}(\text{SDSS}/x)_{\text{M10},\text{SDSS}})$ and $\log_{10}(\sigma_{\text{SF}}(\text{SDSS}/x)_{\text{M10},\text{SDSS}})$, attributed to data-cleaning procedures and software differences, which contributes to a shift between the $C$ and $D$ parameters for $\tau$ and $\sigma_{\text{SF}}$ between M10 and S20.

5.5. Comparison to Other Studies: Eddington Ratio

The Eddington ratio ($f_{\text{Edd}} = L/\lambda_{\text{Edd}}$) encodes accretion strength: the proximity of quasar bolometric luminosity to the theoretical Eddington limit, where $L_{\text{Edd}} = 1.26 \times 10^{38}(M_{\text{BH}}/M_\odot)$ erg s$^{-1}$ (Shen et al. 2011). Since $\tau$ and $\sigma_{\text{SF}}$ depend on $M_i$ and $M_{\text{BH}}$, we investigate the possibility of the Eddington ratio being the driver of these observed trends. In Figure 21, we show $f_{\text{Edd}}$ as a function of $M_i$, $M_{\text{BH}}$, and $\sigma_{\text{SF}}$. The first two panels depict $f_{\text{Edd}}$ and $\sigma_{\text{SF}}$ binned as a function of $M_i$ and $M_{\text{BH}}$. The third panel shows the quasar counts, and the fourth panel shows the bin means (black dots). The means are further binned along $f_{\text{Edd}}$ (as in M10). Combined SDSS–PS1 data support $\sigma_{\text{SF}}$ being inversely related to $f_{\text{Edd}}$ with a power-law slope of $-0.207 \pm 0.03$, consistent with $-0.23 \pm 0.03$ reported by M10. Observations are generally consistent with basic predictions from Table 3: $A$ increases with increasing $M_{\text{BH}}$, and $f_{\text{Edd}}$ decreases as $L_{\text{bol}}$ increases, while $\tau$ increases with $L_{\text{bol}}$. No model from Table 3 is rejected.

In summary, following the standard procedure of shifting the DRW parameter $\tau$ to the quasar rest frame and correcting for wavelength dependence, we compare our results to M10. We show in Figure 10 that the new rest-frame distributions of $\tau$, $\sigma$ with SDSS, SDSS–PS1 are similar to those found by M10. There is a small (<0.05 dex) offset between the parameters fitted for SDSS light curves between this study and M10 that we attribute to data cleaning and software differences (Figure 11). When comparing SDSS and SDSS–PS1 combined data, we expect that there will be a long tail of objects that have a larger timescale and amplitude of variability with an extended baseline, corresponding to a true timescale that is longer than the initially probed time range with SDSS (Figure 12). Changing-look quasars belong to the tail end of quasar variability (Section 5.2), and we suggest 40 candidates in Appendix B, as well as a quick diagnostic plot of differences in mean magnitudes and rms scatter between PS1 and SDSS light-curve portions that could also be used to hunt for CLQSOs independently of DRW fitting (Figure 14). We explore the correlation between the DRW parameters obtained for SDSS and SDSS–PS1 light curves and quasar physical properties. We find that the general trends are in agreement with M10 at the 2$\sigma$ level, with the largest deviations caused by different pipeline procedures, as outlined in Table 2.
Table 3

Theoretical Predictions of Various Models Concerning Amplitude $A$ and/or Timescale $\tau$ of Variability, Eddington Ratio $f_{\text{Edd}}$, Bolometric Luminosity $L_{\text{Bol}}$, and Accretion Rate $\dot{m}$

| Theory                                                                 | Prediction                                                                 |
|-----------------------------------------------------------------------|---------------------------------------------------------------------------|
| Standard thin disk (Shakura & Sunyaev 1973; Netzer 2013)             | $A \sim f_{\text{Edd}}^{-\frac{3}{2}}, \tau \propto L_{\text{Bol}}^{1/2}$ (in Caplar et al. 2017) |
| Strongly inhomogeneous disk (Dexter & Agol 2011)/local fluctuations (Cai et al. 2018) | $A \sim f_{\text{Edd}}$, $\tau \sim L_{\text{Bol}}$                        |
| Variations in global accretion rate (Hawkins 2007; Li & Cao 2008; Zuo et al. 2012) | $A \sim M_{\text{BH}}$, $\tau \sim L_{\text{Bol}}$                        |
| Eddington ratio reflecting AGN age (Martini & Schneider 2003; Hopkins et al. 2005) | $A \sim f_{\text{Edd}}$, $\tau \sim L_{\text{Bol}}$                        |
| X-ray reprocessing (Kubota & Done 2018)                                | $A \sim f_{\text{Edd}}$, and $\tau \sim \dot{m}$                         |

Note. Observations cannot reject any model.

Table 4

Comparison of Published Results on Correlating Observed Quasar Light-curve Properties: A Measure of Variability Amplitude $A$ and Timescale of Variability $\tau$ against the Physical Quasar Properties Black Hole Mass $M_{\text{BH}}$, Eddington Ratio $f_{\text{Edd}}$, and Bolometric Luminosity $L_{\text{Bol}}$

Notes. We list the correlations as positive (+), negative (−, i.e., anticorrelation), not found (0), or not studied (x). We further note whether the correlation is strong (!) or weak (−).

$^a$ The 105,783 quasars with SDSS–PS1 sparse data. SF parameterized as $V_\Delta t (A, \gamma) = (A/\Delta t)^{1/1}$; $\gamma$ is the increase of SF with time lag $\Delta t$.

$^b$ The 90 X-ray-selected AGN, PS1 optical data. Variability characterized by normalized excess variance (EV). PSD characterized by break timescale.

$^c$ Narrow- and broad-line Seyfert 1 AGNs, $z < 0.8$, CRTS data (>50 epochs, 5–9 yr baseline), DRW fitted with JAVELIN (Zu et al. 2011), no timescale correlations considered due to short baseline.

$^d$ The 1004 DDSS quasars with $0.5 < z < 0.89$.

$^e$ The 119,305 sparse quasar light curves from DECaLS and SDSS; SF as in Morganson et al. (2014) above.

$^f$ The 1348 QUEST-La Silla quasars, only amplitude of variability and excess variance.

6. Discussion

6.1. Trends with Eddington Ratio

Anticorrelation of variability amplitude with Eddington ratio has a variety of possible theoretical explanations. In the thin disk theory (Shakura & Sunyaev 1973; Frank et al. 2002; Netzer 2013), the radius of the emission region at a given wavelength increases with Eddington ratio and is inversely proportional to temperature (Rakshit & Stalin 2017). Thus, a hotter disk means that the emission observed in a given bandpass is emitted from a larger radius. From causality, a smaller region can be more variable than a larger one. Therefore, a hotter disk would be less variable at a given wavelength than a colder one, and the variability amplitude as studied in a particular bandpass (here the SDSS $\tau$ band) would be anticorrelated with Eddington ratio (Fausnaugh et al. 2016; Edelson et al. 2015).

On the other hand, in the strongly inhomogeneous disk model, independent temperature fluctuations in $N$ zones drive the variability (Dexter & Agol 2011). In that framework, the inverse trend of variability amplitude against $L/L_{\text{Edd}}$ and $L_{\text{Bol}}$ can be understood qualitatively if more luminous quasars also have a higher mass accretion rate and thus a greater number of disk inhomogeneities, resulting in smaller flux variability (Simm et al. 2016). The inhomogeneous disk model was consistent with mean SDSS spectral analysis in Ruan et al. (2014) but was not a preferred explanation for Kokubo (2015).

Both Rumbaugh et al. (2018; with the Dark Energy Survey SF study) and Sun et al. (2018; with a low-$z$ subsample of S82 SDSS quasars) confirmed the anticorrelation between quasar variability and luminosity. However, Graham et al. (2020) did not find support for this trend with the sample of extremely variable quasars (EVQs) in the CRTS data set, but when selecting for lower-luminosity sources ($M_{V} < -23$), the anticorrelation is recovered. This agrees with an interpretation that a dwindling fuel supply may correspond to higher variability. Furthermore, Sánchez-Sáez et al. (2018) combined the SDSS spectra with the 5 yr light curves of 2345 quasars obtained with the Quasar Equatorial Survey Team (QUEST)-La Silla AGN Variability Survey, and, using the Bayesian parameterization of SF (Schmidt et al. 2010), they also found that the amplitude of variability $A$ is anticorrelated with rest-frame emission wavelength and Eddington ratio (also see Simm et al. 2016; Rakshit & Stalin 2017). See Table 4 for a...
comparison of published studies correlating the statistical measures of observed quasar light curve variability (amplitude/timescale), and the physical quasar properties (black hole mass, bolometric luminosity).

Indeed, \( f_{\text{edd}} \) is a proxy for the strength of accretion, which, together with orientation, may be the key to explaining the quasar main sequence (QMS; Shen & Ho 2014; Marziani et al. 2018). The QMS, defined by so-called Eigenvector-1, is the anticorrelation between the broad-line Fe II emission and the strength of the narrow O \( \text{III} \) (5007 Å) line (Wang et al. 1996). An analysis of quasar clustering by Shen & Ho (2014), later confirmed by Sun & Shen (2015) with measurements of black hole mass from the quasar host galaxy stellar dispersion (Ferrarese & Merritt 2000; Kormendy & Ho 2013), showed that the entire diversity of quasars in the QMS can be explained by the variation in accretion (affecting \( R_{\text{FeII}} \)), the ratio of the Fe II equivalent width between 4435 and 4685 Å and \( H_{\beta} \) or orientation effects (affecting the FWHM of the \( H_{\beta} \)). However, Panda et al. (2019a, 2019b) found that these are sufficient, and variations in metallicity, as well as a range of cloud densities and turbulences, are required. Jiang et al. (2016) also found that metallicity, and in particular the iron opacity bump, may have a strong influence on the stability of an accretion disk, thus linking metallicity to AGN variability. This is also consistent with the findings of Sun et al. (2018): quasars with high Fe II strength have higher metallicity and more stable disks.

6.2. Variability Timescales

In the era of changing-look active galaxies (including initially distinct classes of changing-look quasars (LaMassa et al. 2015; MacLeod et al. 2019), changing-look AGNs (CLAGNs; Bianchi et al. 2009; Risaliti et al. 2009; Marchese et al. 2012), and changing-look LINERS (Frederick et al. 2019, to name a few), there is a revived interest in possibly linking the behavior of stellar-sized accreting systems (e.g., black hole binaries) to that of galactic-scale systems (e.g., AGNs, QSOs, and LINERS; Noda & Done 2018; Ruan et al. 2019).

Several relevant timescales are involved, and there are various interlinked mechanisms that could drive the variability. A standard optically thick, geometrically thin, \( \alpha \)-disk model has a hierarchy of timescales: dynamical, thermal, front, and viscous, with \( t_{\text{dyn}} < t_{\text{th}} < t_{\text{front}} < t_{\text{visc}} \) (Netzer 2013; Frank et al. 2002). We proceed to briefly describe each timescale, concluding with our interpretation of the mechanism that could drive the variability observed from the data.

The dynamical, or gas orbital, timescale is simply an inverse of the Keplerian orbital angular frequency \( \Omega \) at radius \( R \):

\[
 t_{\text{dyn}} \sim 1/\Omega = \left( \frac{GM}{R^3} \right)^{-1/2}. \tag{13}
\]

The main parameter describing the accretion disk is \( \alpha \), the ratio of the (vertically averaged) total stress to thermal (vertically averaged) pressure:

\[
 \alpha = \frac{\langle \tau_{\nu z} \rangle}{\langle P \rangle}. \tag{14}
\]

After Lasota (2016), the hydrodynamical stress tensor (corresponding to kinematic viscosity \( \nu \)) is

\[
 \tau_{\nu z} = \rho \nu \frac{d\nu}{dR} = \rho \nu \frac{d\Omega}{d\ln R} = \frac{3 \rho \nu \Omega}{2}, \tag{15}
\]

so with \( c_s \) (local sound speed) at radius \( R \) (isothermal sound speed is \( c_s = \sqrt{P/\rho} \)).

\[
 \alpha = \frac{3 \rho \nu \Omega}{2P} = \frac{3 \Omega \nu}{2c_s^2}. \tag{16}
\]

This means that a smaller \( \alpha \) corresponds to less viscous disks.

The thermal timescale, related to the time needed for readjustment to the thermal equilibrium (derived in detail in Frank et al. 2002), is the ratio of heat content per unit disk area to dissipation rate per unit disk area: \( \frac{dE}{dt} / A \). The heat content per unit volume is \( \sim \rho c_s^2 / h \), and the heat content per unit area is \( \sim \rho c_s^2 / h \sim \Sigma c_s^2 \). Meanwhile, the dissipation rate per unit area, \( D(R) \), is

\[
 D(R) = \frac{9}{8} \nu \Sigma R^{-3} GM \tag{17}
\]

(Equation 4.30 in Frank et al. 2002), so

\[
 t_{\text{th}} \sim \frac{c_s^2 R^3}{GM\nu} = \frac{c_s^2}{\nu \Omega} = t_{\text{dyn}}/\alpha. \tag{18}
\]

Thus, if the disk is inviscid (\( \nu \rightarrow 0 \)), then \( t_{\text{th}} \rightarrow \infty \); i.e., there is no contact with adjacent disk elements.

The cooling and heating fronts propagate through the disk at \( \alpha c_s \) (Hameury et al. 2009); in that description, with no viscosity, there is no communication between neighboring disk annuli and thus no front propagation (Balbus & Hawley 1998; Balbus 2003). Following Stern et al. (2018), if we define the disk aspect ratio as \( h/R \) with a disk height \( h = c_s/\Omega \), the characteristic time for front propagation is

\[
 t_{\text{front}} \sim (h/R)^{-1} t_{\text{th}}. \tag{19}
\]

The viscous timescale is the characteristic time it would take for a parcel of material to undergo radial transport due to the viscous torques from the radius \( R \) to the black hole (Czerny 2006). Note that while viscosity probably has a magnetic origin (Eardley & Lightman 1975; Grzegor zwiecki et al. 2017), in this simplistic order-of-magnitude estimate, we use a hydrodynamical description of accretion flow. With \( \nu = \eta / \rho \) (kinematic viscosity being the ratio of dynamical viscosity to density), Frank et al. (2002) showed (chapter 5.2) that

\[
 t_{\text{visc}} \sim R^2 / \nu \sim R/\nu = (h/R)^{-2} t_{\text{th}}. \tag{20}
\]

We can parameterize each timescale for a black hole mass \( M_{\text{BH}} = 10^8 M_\odot \) at \( R \sim 150 r_g \), with the gravitational radius \( r_g = G M_{\text{BH}} / c^2 \sim 4 \text{ au} \), using Equations (5)–(8) in Stern et al. (2018):

\[
 t_{\text{dyn}} \sim 10 \text{days} \left( \frac{M_{\text{BH}}}{10^8 M_\odot} \right) \left( \frac{R}{150 r_g} \right)^{3/2}, \tag{21}
\]

\[
 t_{\text{th}} \sim 1 \text{yr} \left( \frac{\alpha}{0.03} \right)^{-1} \left( \frac{M_{\text{BH}}}{10^8 M_\odot} \right) \left( \frac{R}{150 r_g} \right)^{3/2}, \tag{22}
\]

\[
 t_{\text{front}} \sim 20 \text{yr} \left( \frac{h}{R} \right)^{-1} \left( \frac{\alpha}{0.03} \right)^{-1} \left( \frac{M_{\text{BH}}}{10^8 M_\odot} \right) \left( \frac{R}{150 r_g} \right)^{3/2}, \tag{23}
\]
\[
\tau_{\text{visc}} \sim 400 \text{yr} \left( \frac{h/R}{0.05} \right)^2 \left( \frac{\alpha}{0.05} \right)^{-1} \times \left( \frac{M_{\text{BH}}}{10^8 M_{\odot}} \right) \left( \frac{R}{150 r_g} \right)^{3/2}.
\]

(24)

In summary, of the considered timescales, only the thermal and dynamical are short enough to be related to the observed short-term stochastic variability. It may be that the variability on the scale of days is driven by local changes and that on the longer scale (perhaps hundreds of days) by a different mechanism (Kokubo 2015). The other timescales may be more related to the dramatic changes in brightness of the continuum as observed in changing-look AGNs. Indeed, Noda & Done (2018) favored a change in mass accretion rate, followed by a propagation of the cooling front (Simm et al. 2016; Lawrence 2018). Noda & Done (2018) also suggested that perhaps some short-term variability could be related to the amount of the disk swept by the thermal front propagation due to hydrogen ionization instability, similar to white dwarf systems (see also Ross et al. 2018; Ruan et al. 2019; Śniegowska & Czerny 2019).

The variability on a several-year timescale could also be explained by the X-ray reprocessing model (Kubota 2015; Kubota & Done 2018), assuming that the AGN UV–optical variability is a result of reprocessing of X-ray or far-UV emission (Krolik et al. 1991). The idea of X-ray reprocessing over time has gained more and more support, with evidence from simultaneous X-ray–UV–optical AGN time series (Edelson et al. 2014; McHardy et al. 2018; Zhu et al. 2018). In particular, the accretion disk blackbody emission is insufficient to explain the broadband AGN spectrum. The total spectral energy distribution with a soft X-ray excess and a hard X-ray tail requires additional sources of emission. A recent model by Kubota & Done (2018) divides the flow into blackbody emission, a warm Comptonization region (the disk), and a hard X-ray hot Comptonization component (the corona, or a hot material filling the region close to the black hole below the truncation radius). Since the soft X-rays are correlated with the hard X-rays, at least at part of the picture consists of reflection or reprocessing of hard X-rays by the disk (Lawrence 2018). This model predicts an increase of variability amplitude \( \langle SF_{\text{var}} \rangle \) with \( M_{\text{BH}} \) and adds the insight that the observed slope is due to changes in accretion rate \( m \), explaining that smaller \( m \) corresponds to the highest variability. This qualitatively agrees with the picture that a dwindling fuel supply makes the flow more variable. Previous worries about X-ray reprocessing concerned the seemingly insufficient solid angle subtended by the source of the hard X-rays to cause the observed soft X-ray and optical response. This is addressed by realizing that reprocessing could be taking place in the extended region (Gardner & Done 2017), such as an inflated inner disk (corresponding to a warm Comptonizing region in Kubota & Done 2018), or even the BLR region, serving as an additional “complex reprocessor” (McHardy et al. 2018). Also, for Panda et al. (2019a), a warm corona helps decrease the dependence of \( R_{\text{eff}, 2} \) on \( f_{\text{edd}} \).

Thus, while CLAGN may be related to the state change to advection-dominated accretion flow (Śniegowska & Czerny 2019), similar to that of X-ray binaries (Noda & Done 2018; Ruan et al. 2019), with cooling and heating fronts (Ross et al. 2018), the short-timescale variability requires approximately three distinct emission regions (Kubota & Done 2018) with an extended reprocessor (such as a diffuse, hot, puffed-up inner disk and BLR; McHardy et al. 2018) that reverberates the rapid hard X-ray variability in soft X-rays to the optical via UV (Faunsaugh et al. 2018). Some emission (especially soft X-rays) seems to require the warm Comptonizing corona (Kubota & Done 2018). The warm corona, coupled with metallicity changes and variation in turbulence level and cloud density, also helps explain the QMS in the optical (Panda et al. 2019a, 2019b). Finally, the Kubota & Done (2018) model, apart from being consistent with other mechanisms (Lawrence 2018; McHardy et al. 2018; Ross et al. 2018; Panda et al. 2019a; Ruan et al. 2019; Śniegowska & Czerny 2019), explains the observed correlation of variability amplitude with black hole mass as corresponding to variations in mass accretion rate.

7. Summary and Conclusions

We model the optical variability of \( \sim 9000 \) S82 quasars as the DRW (Kelly et al. 2009). The DRW is a GP, described by two parameters: characteristic timescale \( \tau \) (representing the decorrelation timescale, or light-curve smoothness) and asymptotic amplitude \( SF_{\infty} \) (which relates to the amplitude of variability). We fit observed and simulated light curves with celerite, a fast GP solver (Foreman-Mackey et al. 2017). By simulating and fitting DRW light curves, we explore the impact of the ratio of input timescale and light-curve baseline. We find that the light-curve length needs to be several times larger than the input timescale to allow unbiased timescale retrieval, confirming K17. Motivated by this result, we consider extending SDSS with PS1, PTF, CRTS, and ZTF data. We calculate appropriate photometric offsets (color terms) to relate PS1 gri, PTF gr, CRTS V, and ZTF r to the SDSS r band. However, due to larger photometric uncertainties of PTF, ZTF, and CRTS at the faint magnitudes of SDSS quasars, we decided to use only PS1 r-band data. Furthermore, the SDSS and PS1 r bands are sufficiently similar that no photometric transformation is required. Thus, by extending the SDSS r-band light curves with PS1 DR2 r-band data, we improve upon the fidelity of recovered DRW parameters (e.g., in Figure 9, showing a simulated population of \( \tau = 575 \) days, the rms of \( \log(\tau_{\text{obs}}/\text{baseline}) \) decreases from 1.75 dex with SDSS to 1.5 dex with PS1, and in the future, with the inclusion of ZTF and LSST data, it will decrease to \( \sim 1 \) dex).

We identify 40 objects that exhibit a tenfold increase in variability timescale when using the SDSS–PS1 data set, as compared to the timescale inferred from SDSS alone. Their light curves show characteristics of changing-look quasars (magnitude difference larger than 0.5 mag; MacLeod et al. 2016). Of these, five are confirmed in the literature (MacLeod et al. 2019; LaMassa et al. 2015). We recommend spectroscopic follow-up and further monitoring of the brightest targets (see Appendix B).

We investigate the correlation of quasar physical properties, such as black hole mass \( M_{\text{BH}} \) and absolute i-band magnitude \( M_i \) with DRW model parameters. The SDSS–PS1 data, coupled with the Shen et al. (2011) quasar catalog, imply that the damping timescale \( \tau \) is correlated with \( M_{\text{BH}} \) with a power-law index of 0.141 ± 0.019 and almost independent of quasar bolometric luminosity as in M10, Willhite et al. (2008), and Vanden Berk et al. (2004). The asymptotic variability amplitude \( SF_{\infty} \) is correlated with \( M_i \) (i.e., anticorrelated with luminosity) with a power-law index of 0.118 ± 0.003 and \( M_{\text{BH}} \) with a slope of 0.118 ± 0.008. This can be explained if the driving variable was the Eddington ratio, \( \lambda_{\text{edd}} \) (Willhite et al. 2008). Indeed, there is an anticorrelation of \( SF_{\infty} \) and \( f_{\text{edd}} \) with a power-law slope of
–0.207 ± 0.031 (similar to M10). As suggested by Kubota & Done (2018), this gradient of $S_{\infty}$ in the plane of $M_{BH}$ versus $M_{*}$ could be explained if the lower mass accretion rate corresponds to higher variability, so that when the supply of fuel decreases, the flow becomes less stable and more clumpy and inhomogeneous (Rakshit & Stalin 2017; Kobuko 2015; Dexter & Agol 2011). This is also consistent with the X-ray reprocessing model, whereby the hard X-ray variability of the inner disk is reprocessed by the extended warm Comptonization region (inflated disk) and perhaps a complex reprocessor, including the clouds of the BLR (Kubota & Done 2018; Pandya et al. 2019b).

Changes on recovered timescales are too fast to be driven by changes in disk viscosity or thermal front propagation alone; a thermal or dynamical timescale of response to the changes in X-ray emission seems most consistent with our results (Stern et al. 2018).

More data extending the light curves would help improve the DRW fit coefficients, potentially decreasing the scatter in the observed correlations—for instance, for simulated $r$ recovery, an improvement of the rms by a factor of 1.8 (from 0.322 for SDSS only to 0.182 with combined SDSS–PS1–ZTF–LSST). Moreover, given that the uncertainty in black hole mass is one of the biggest sources of error, better measurements of quasar properties would be of high utility (Shen et al. 2011). This will be possible with the upcoming AGN reverberation mapping campaigns (e.g., SDSS-V black hole mapper), providing better calibration for line width–based methods of estimating black hole masses (Kollmeier et al. 2017). All quasars in this study were spectroscopically confirmed, but some spectra had low signal-to-noise ratios, resulting in a higher likelihood of incorrect redshift measurement. Better spectroscopy and follow-up of S82 quasars, afforded by SDSS-V panoptic spectroscopy, would not only help improve on the spectrum-based properties (redshift, absolute magnitude, black hole masses) but also allow the study of spectral changes and further new CLAGN discoveries (MacLeod et al. 2019).

If this study were to be expanded onto a sample of quasars with good photometry over sufficiently long baselines but lacking spectral information, the required physical information on quasars could be obtained by indirect methods of estimating the coarse spectral information from broadband photometry (Kozlowski 2015). This would benefit from better catalogs of existing spectroscopically confirmed quasars (SDSS DR14) to improve the calibration, as well as better methods of estimating the redshift based on photometry alone (e.g., photo-$z$; Richards et al. 2015; Yang et al. 2017; Curran & Moss 2019; Jin et al. 2019). This will be possible in the short term with the ZTF (Bellm et al. 2019) and in the long term with the LSST (Ivezić et al. 2019). Occasional coverage adding a few epochs to some quasars may be possible with other surveys (e.g., TESS; Ricker et al. 2014), but to improve the statistics of an entire sample of S82 quasars would require longer baselines. Combining SDSS and PS1 with LSST would provide an unprecedented 35 yr baseline, which, assuming timescales below 1000 days, is over 10 times longer, allowing unbiased DRW parameter retrieval. This, coupled with correlations with quasar properties, would provide an estimate of black hole masses and bolometric luminosities for millions of quasars (Ivezić et al. 2019).

The Pan-STARRS1 Surveys (PS1) and the PS1 public science archive have been made possible through contributions by the Institute for Astronomy, the University of Hawaii, the Pan-STARRS Project Office, the Max Planck Society and its participating institutes, the Max Planck Institute for Astronomy, Heidelberg, and the Max Planck Institute for Extraterrestrial Physics, Garching, The Johns Hopkins University, Durham University, the University of Edinburgh, the Queen’s University Belfast, the Harvard-Smithsonian Center for Astrophysics, the Las Cumbres Observatory Global Telescope Network Incorporated, the National Central University of Taiwan, the Space Telescope Science Institute, the National Aeronautics and Space Administration under grant No. NNX08AR22G issued through the Planetary Science Division of the NASA Science Mission Directorate, National Science Foundation grant No. AST-1238877, the University of Maryland, Eotvos Lorand University (ELTE), the Los Alamos National Laboratory, and the Gordon and Betty Moore Foundation.

Funding for the Sloan Digital Sky Survey IV has been provided by the Alfred P. Sloan Foundation, the U.S. Department of Energy Office of Science, and the Participating Institutions. The SDSS-IV acknowledges support and resources from the Center for High-Performance Computing at the University of Utah. The SDSS website is www.sdss.org. The SDSS-IV is managed by the Astrophysical Research Consortium for the Participating Institutions of the SDSS Collaboration including the Brazilian Participation Group, the Carnegie Institution for Science, Carnegie Mellon University, the Chilean Participation Group, the French Participation Group, the Harvard-Smithsonian Center for Astrophysics, Instituto de Astrofísica de Canarias, The Johns Hopkins University, the Kavli Institute for the Physics and Mathematics of the Universe (IPMU)/University of Tokyo, the Korean Participation Group, Lawrence Berkeley National Laboratory, Leibniz Institut für Astrophysik Potsdam (AIP), Max-Planck-Institut für Astronomie (MPIA Heidelberg), Max-Planck-Institut für Astrophysik (MPA Garching), Max-Planck-Institut für Extraterrestrische Physik (MPE), National Astronomical Observatories of China, New Mexico State University, New York University, the University of Notre Dame, Observatório Nacional/MCTI, The Ohio State University, Pennsylvania State University, Shanghai Astronomical Observatory, the United Kingdom Participation Group, Universidad Nacional Autónoma de México, the University of Arizona, the University of Colorado Boulder, the University of Oxford, the University of Portsmouth, the University of Utah, the University of Virginia, the University of Washington, the University of Wisconsin, Vanderbilt University, and Yale University.

The CSS survey is funded by the National Aeronautics and Space Administration under grant No. NNG05GF22G issued through the Science Mission Directorate Near-Earth Objects Observations Program. The CRTS survey is supported by the U.S. National Science Foundation under grant AST-0909182.

Based on observations obtained with the Samuel Oschin 48 inch telescope at the Palomar Observatory as part of the Zwicky Transient Facility project. The ZTF is supported by the National Science Foundation under grant No. AST-1440341 and a collaboration including Caltech, IPAC, the Weizmann Institute for Science, the Oskar Klein Center at Stockholm University, the University of Maryland, the University of Washington, Deutsches Elektronen-Synchrotron and Humboldt University, Los Alamos National Laboratories, the TANGO Consortium of Taiwan, the University of Wisconsin at Milwaukee, and Lawrence Berkeley National Laboratories. Operations are conducted by COO, IPAC, and UW.
Appendix A
Measuring Quasar Properties

In this work, we employ black hole masses, bolometric luminosities, and $k$-corrections from the Shen et al. (2011) catalog based on single-epoch SDSS spectra. Here we explain the choices made in the difficult art of estimating each of these quasar physical properties.

It is nontrivial to measure the mass of black holes living in the centers of active galaxies, even provided with a detailed spectrum. The most common approach to estimate black hole masses in AGNs is to assume that the BLR is virialized,

$$M_{\text{BH}} = f \frac{R \Delta V^2}{G} = f M_{\text{vir}},$$  \hspace{1cm} (A1)

where $f$ is a constant of order unity, $R$ is the size of the BLR (estimated from emission line lag $\Delta t$ as $R = c \Delta t$), $\Delta V$ is the virial velocity, and $G$ is the gravitational constant (Shen et al. 2008). From reverberation mapping (RM) studies (e.g., Shen et al. 2019), we know that continuum luminosity $L$ is related to the size of the BLR region as $R \propto L^{1/3}$ (Vestergaard & Peterson 2006), with $\gamma$ very close to 1/2 (e.g., Bentz et al. 2009) found from RM studies $\gamma = 0.519 \pm 0.06$. Thus, we find that $R^2 \Delta V^2 \propto L^{1/3} \Delta V^2 \equiv \mu$. The virial velocity $\Delta V$ is usually estimated from the width of the broad emission lines (or line dispersion). In the absence of a quasar spectrum, there are alternative methods using a conversion of the broadband photometry into monochromatic fluxes in the vicinity of reverberating lines (e.g., Kozłowski 2015, used in Kozłowski 2017b to estimate black hole masses for 280,000 AGNs). Depending on the redshift, different rest-frame calibrated emission lines shift into the observed passband: broad H$\alpha$ at 6562 Å, H$\beta$ at 5100 Å, Mg II at 2800 Å, and C IV at 1350 Å (see Figure 7 in Shen et al. 2019 and Vestergaard 2002). Some authors even separately consider CIV- and Mg II-based black hole mass estimates. We refer the reader to Shen et al. (2008), who described in detail the various biases and inherent assumptions of virial black hole mass measurements.

Another important quasar property, bolometric luminosity, is most often estimated from the absolute $i$-band magnitude, $M_i$ (see Shen et al. 2008, Figure 2). Here $M_i$ is derived from the observed $i$-band magnitude by correcting for Galactic extinction and the fact that at different redshifts, different portions of the spectral energy distribution are observed by the telescope filter bandpass. The latter, known as $k$-correction $K(z)$ (Oke & Sандage 1968), is defined as $m_{\text{intrinsic}} = m_{\text{observed}} - K(z)$. In the early 2000s, the common approach was to $k$-correct to a redshift of zero, but as Richards et al. (2006) pointed out, since the distribution of quasars peaks at a redshift of 2, for most quasars, correcting to a redshift of zero required shifting the observed spectrum into the far-infrared. Moreover, the procedure was to correct separately for the continuum and emission line contributions, assuming a particular spectral shape (e.g., power law $f_\nu \propto \nu^{\alpha}$, with $\alpha = -0.5$; see Vanden Berk et al. 2001; Richards et al. 2006; Schneider et al. 2010). This introduces a larger error for $K(z = 0)$ than for $K(z = 2)$ if the assumed spectral shape $\alpha = -0.5$ is far from the real spectral index. In early 2010s, after Richards et al. (2006), Wisotzki (2000), and Blanton et al. (2003), the practice started shifting toward $k$-correcting to a redshift of 2 and including custom quasar spectral shapes, as reflected by the content of the Shen et al. (2011) quasar catalog. Thus, in this study, we use the absolute $i$-band magnitude $k$-corrected to $z = 2$: $M_i(z = 2)$.

These methods were used to create catalogs of quasar properties derived from spectra. Since quasars are variable at the $\sim 0.2$ mag level, the ideal is to use a single-epoch calibrated spectrum to estimate the continuum luminosity and find virial black hole masses using relationships based on the monochromatic fluxes and broad line widths described above. A glance at the available quasar catalogs reveals that, given any SDSS data release, there is indeed a catalog of basic quasar properties (redshift and photometry; e.g., Schneider et al. 2007, 2010), and more detailed catalogs containing black hole masses and bolometric luminosities follow (e.g., Shen et al. 2008, 2011). More recently, once the SDSS DR12 Quasar Catalog (Pâris et al. 2017) was released, K17 followed using SDSS photometry as a proxy for monochromatic luminosities. Chen et al. (2018) added a detailed analysis of continuum luminosities in the H$\alpha$, H$\beta$ regions for low-redshift quasars. Using the spectra from the Chinese LAMOST survey, Dong et al. (2018) also sought to estimate virial black hole masses, and the results, while consistent with Shen et al. (2011), suffered from the necessity of pegging the noncalibrated spectra to the SDSS photometry, which was taken a different epoch. Thus, even though the SDSS DR12 Quasar Catalog of Pâris et al. (2018) is the most recent, like Pâris et al. (2017), it lacks black hole masses and bolometric luminosities, and there is no recent work that reanalyzed the spectral data. Therefore, we use black hole mass estimates and monochromatic luminosities from Shen et al. (2011) based directly on single-epoch spectra.

Appendix B
CLQSO Candidates

Based on the DRW model parameters $\tau$, $\sigma$ fitted with celerite using the SDSS and PS1 data, we find that there are quasars for which there is a pronounced difference between $\tau$, $\sigma$ inferred from combined SDSS–PS1 data versus just SDSS. Specifically, Figure 12 shows that there are objects where $f_\tau = \log_{10}(\sigma_{\text{SDSS–PS1}}/\sigma_{\text{SDSS}}) > 0.4$ and $f_\sigma = \log_{10}(\tau_{\text{SDSS–PS1}}/\tau_{\text{SDSS}}) > 1$ (a tenfold increase in $\tau$ and over twofold increase in $\sigma$). Visual inspection of objects simultaneously satisfying $f_\tau > 0.4$ and $f_\sigma > 1$ shows that these underwent a significant (>0.5 mag) change in brightness between the SDSS (baseline 1998–2008) and PS1 DR2 observations (2009–2014; see Figure 2). Thus, DRW fitting could also be a way of finding changing-look quasar (and AGN) candidates. Figure 22 shows the SDSS–PS1 $r$-band light curves of 40 CLQSO candidates with median PS1 brightnesses larger than 20.5 mag. The open circles indicate day-averaged epochs (see Section 3). Table 5 contains the basic physical parameters for these quasars. Some quasars show a downward trend, like turn-off CLQSOs (e.g., 123909, 1412379, and 1644710), while some are seen in a brightening stage, like turn-on CLQSOs (e.g., 1976348, 221006, 4069419, and 4205621). Quasar 612585 has the largest amount of auxiliary multiwavelength coverage—X-ray from XMM-Newton, UV from the Galaxy Evolution Explorer (GALEX), and IR from the UKIRT Infrared Deep Sky Survey (UKIDSS), VHS, and the Wide-field Infrared Survey Explorer (WISE)—and has been analyzed as part of the X-ray-targeted sample of S82 quasars, S82X, by LaMassa et al. (2016). Quasar 751557 was previously identified by MacLeod et al. (2019) as a CLQSO candidate, with detailed Magellan spectroscopy described therein. Two quasars, 1003694 and 1299803, have WISE data previously identi
development.

Based on the DRW model parameters $\tau$, $\sigma$ fitted with celerite using the SDSS and PS1 data, we find that there are quasars for which there is a pronounced difference between $\tau$, $\sigma$ inferred from combined SDSS–PS1 data versus just SDSS. Specifically, Figure 12 shows that there are objects where $f_\tau = \log_{10}(\sigma_{\text{SDSS–PS1}}/\sigma_{\text{SDSS}}) > 0.4$ and $f_\sigma = \log_{10}(\tau_{\text{SDSS–PS1}}/\tau_{\text{SDSS}}) > 1$ (a tenfold increase in $\tau$ and over twofold increase in $\sigma$). Visual inspection of objects simultaneously satisfying $f_\tau > 0.4$ and $f_\sigma > 1$ shows that these underwent a significant (>0.5 mag) change in brightness between the SDSS (baseline 1998–2008) and PS1 DR2 observations (2009–2014; see Figure 2). Thus, DRW fitting could also be a way of finding changing-look quasar (and AGN) candidates. Figure 22 shows the SDSS–PS1 $r$-band light curves of 40 CLQSO candidates with median PS1 brightnesses larger than 20.5 mag. The open circles indicate day-averaged epochs (see Section 3). Table 5 contains the basic physical parameters for these quasars. Some quasars show a downward trend, like turn-off CLQSOs (e.g., 123909, 1412379, and 1644710), while some are seen in a brightening stage, like turn-on CLQSOs (e.g., 1976348, 221006, 4069419, and 4205621). Two quasars, 1003694 and 1299803, have WISE data previously identi
development.
3633437 have X-ray detections in the 3XMM DR5 catalog (Rosen et al. 2016), but they have no matches in the Chandra point-source catalog (second release; Evans et al. 2010; Evans & Civano 2018). There are no matches against the unified radio catalog of Kimball & Ivezić (2008), which includes FIRST and NVSS data. We especially recommend spectroscopic follow-up of the brightest targets: 1976348 (mean 17.8 mag, turn-on) and 2104791 (mean 18.4 mag, turn-off); see Figure 22.

Figure 22. Outliers in the space of the recovered DRW parameters between SDSS and SDSS–PS1, as well as median offsets.
Figure 22. (Continued.)
Figure 22. (Continued.)
Figure 22. (Continued.)
We searched for the dependency of variability parameters on other physical properties beyond the black hole mass and quasar luminosity employed in Equation (12). The quasar optical spectrum has certain strong emission lines, depending on the redshift. In particular, the Mg II emission line lags the continuum and is less variable (Reichert et al. 1994). The Mg II line is also an important virial black hole mass estimator for quasars; McLure & Jarvis (2002) noticed that the FWHM of the Mg II doublet trails that of the H/β line (also see Shen 2013).

Following Ivezić et al. (2004) and MacLeod et al. (2012), we investigated the residuals after fitting the model (Equation (12), $\text{SF}_\infty$) to the SDSS-PS1 data as a function of wavelength. The left panel of Figure 23 shows the $\text{SF}_\infty$ model residuals in the $\lambda_{RF}$ versus $\tau_{RF}$ space. The right panel shows the residuals marginalized along $\tau_{RF}$. The decrement around 2800 Å is more pronounced when using combined SDSS–PS1 light curves. We see that both aggregates based on raw data (blue dots) or medians (black dots) agree; the two statistical methods show a small ($\sim$5%) but statistically significant detection of a depression in the 2800 Å region, as expected from theory.
Figure 23. The residuals ($\zeta$) after fitting Equation (12) to the quasar SF$_\infty$ using SDSS–PS1 quasar light curves. The left panel shows the residuals as a function of $\lambda_{RF}$ and $\tau_{RF}$. The right panel shows the median of the residuals marginalized along $\tau_{RF}$, with an error on the median based on the scatter in the $\lambda_{RF}$ bins, $\sigma_{median} = 1.25\, \text{RMS}_\text{median}/\sqrt{N_{\text{bins}}}$, where $\text{RMS}_{\text{median}}$ is estimated from the robust Gaussian interquartile-based $\sigma_{G}$ (Ivezić et al. 2014). Black dots are medians based on the averages plotted on the left ($N_{\text{bins}}$ is between 7 and 20, depending on the number of nonempty bins in the left panel), and blue dots are medians based on the raw data ($N_{\text{bins}}$ varies as a function of $\lambda_{RF}$, from a few to 800, peaking at about 2500 Å, reflecting the fact that the quasar distribution peaks at redshift $z = 2$). We overplot the composite quasar spectrum from Vanden Berk et al. (2001) and mark the location of the Mg II 2798 Å line with a vertical dashed red line.
