When the semiclassical Herman–Kluk propagator is used for evaluating quantum-mechanical observables or time-correlation functions, the initial conditions for the guiding trajectories are typically sampled from the Husimi density. Here, we employ this propagator to evolve the wavefunction itself. We investigate two grid-free strategies for the initial sampling of the Herman–Kluk propagator applied to the wavefunction and validate the resulting time-dependent wavefunctions evolved in harmonic and anharmonic potentials. In particular, we consider Monte Carlo quadratures based either on the initial Husimi density or on its square root as possible and most natural sampling densities. We prove analytical convergence error estimates and validate them with numerical experiments on the harmonic oscillator and on a series of Morse potentials with increasing anharmonicity. In all cases, sampling from the square root of Husimi density leads to faster convergence of the wavefunction.

quantum propagator, time-dependent semiclassical approximation, highly oscillatory integral, statistical convergence of Monte Carlo methods, mesh-free discretization

1 Introduction

Semiclassical initial value representation techniques [1, 2] have evolved into useful tools for calculations of the dynamics of atoms and molecules [3]. Frozen Gaussians and their superposition were introduced by Heller in 1981 [4] as an extension to the thawed Gaussian approximation [5] in order to capture non-linear spreading of the wavepackets. Herman and Kluk justified the frozen-Gaussian ansatz and introduced an improved approximation [6–8], now known as the Herman–Kluk propagator, which contains an additional prefactor that rigorously compensates for the fixed width of these frozen Gaussians and ensures unitarity of the time evolution in the stationary-phase limit [7]. The Herman–Kluk approximation keeps the trajectories of the individual Gaussians uncoupled, which sets it apart from the more accurate, but computationally more demanding approaches like the coupled coherent states [9] or the variational multi-configurational Gaussian method [10].

In the spirit of the semiclassical initial value representation, the Herman–Kluk propagator avoids the root search problem [2, 11]. Because of its high accuracy, this propagator belongs among the most successful semiclassical approximations [12–18] and has been derived in many different ways [9, 19–22]. There are observables, such as low-resolution vibronic spectra in mildly anharmonic systems, which can be well described by the more efficient thawed Gaussian approximation [23, 24] and other single-trajectory methods [25–30]. In chaotic and other systems, however, increased anharmonicity leads to wavepacket splitting and non-trivial interference effects. In such
filinov

required by the Herman

various methods, whose goal is reducing the number of trajectories. For this reason, several groups designed

converged computations might require an extremely large

not only its advantage, but also its bottleneck. In particular,

higher-order semiclassical corrections to the

Herman–Kluk propagator. These include, e.g.,

semiclassical interaction picture [42, 43],

hybrid dynamics [45–47],

and many others, which achieve the reduction in the number

of trajectories by applying one of several possible further

approximations.

Yet, the number of guiding trajectories can already be

significantly reduced simply by choosing the sampling density

of the initial conditions wisely. Although the acceleration of the

convergence may be smaller than with the previously mentioned

approximate methods, the advantage of this "purely numerical" approach based on improved exact sampling of the unaltered

Herman–Kluk initial value representation is that the converged

results agree exactly with the converged results of the original

Herman–Kluk propagator. For this reason, an early numerical

study [8] of the Herman–Kluk wavefunction employed the square

root of the Husimi distribution as the sampling density of the

initial state, whereas most calculations of observables, time-
correlation functions, and wavepacket autocorrelation functions,

i.e., quantities quadratic in the wavefunction, correctly employ sampling from the Husimi density [2, 51]. In

contrast to observables and correlation functions, the

Herman–Kluk wavefunction itself has not been studied much

since the early papers [6, 8] and rigorous numerical analysis has

been presented only recently [52, 53]. However, the choice of the

optimal sampling density for the Herman–Kluk wavefunction

itself has not been analyzed in detail.

The goal of this work is, therefore, to analyze the

convergence of the Herman–Kluk wavefunction for different

initial sampling strategies and to understand the convergence

error as a function of time. Specifically, we investigate two

mesh-free discretization approaches for the initial

sampling—first analytically and then numerically on the

examples of harmonic and Morse oscillators with increasing

anharmonicity. In a follow-up paper, an analogous detailed

analysis of the convergence of the norm, energy, and other

expectation values will be presented.

The remainder of this paper is organized as follows. In

the next section we briefly introduce the Herman–Kluk propagator

and its components necessary for numerical computations. We

define the initial sampling densities and specify the algorithm

used for numerical experiments. In the main

Section 3, we analyze the errors at the initial and final times due to the

phase-space discretization. In particular, we prove that in the

harmonic oscillator this error is a periodic function of time. Our

numerical experiments in Section 4 confirm the theoretical error

estimates and provide further insights into the anharmonic

evolution generated by Morse potentials, which are not

accessible to explicit analytical calculations.

2 Discretising the Herman–Kluk

propagator

2.1 Herman–Kluk propagator

Evolution of a quantum state \(|\psi(t)\rangle\) is governed by the time-dependent Schrödinger equation

$$i\hbar \frac{d}{dt} |\psi(t)\rangle = \hat{H} |\psi(t)\rangle, \quad |\psi(0)\rangle = |\psi_0\rangle$$

(1)

where \(\hbar\) is the reduced Planck constant and \(\hat{H}\) is the Hamiltonian

operator. Here, we assume the Hamiltonian to be the time-

independent operator

$$\hat{H} = \frac{1}{2m} \hat{p}^2 + V(\hat{q}),$$

(2)
where $m$ is the mass (after mass-scaling coordinates), and $q$ and $p$ are $D$-dimensional position and momentum vectors. Under the usual regularity and growth assumptions on the potential energy function $V$, the spectral-theorem [54] provides for all times $t \in \mathbb{R}$ a well-defined unitary propagator

$$U_t := \exp(-i\hat{H}t/\hbar),$$

in terms of which the solution of (1) can be expressed as

$$|\psi(t)\rangle = U_t|\psi_0\rangle$$

for all square integrable initial data $|\psi_0\rangle = \langle x|\psi_0\rangle \in L^2(\mathbb{R}^D)$.

Solving the Schrödinger equation numerically is notoriously difficult for various reasons. With respect to the atomic scale, the nuclear mass is rather large, so that the presence of the factor $m^{-1}$ in the kinetic energy operator induces highly oscillatory motion both with respect to time and space. More importantly, for most decompositions of our solution of the time-dependent Schrödinger equation

$$V_{\alpha\beta}(z) = \left(\begin{array}{cc} 0 & \hat{d}_\alpha \\ -\hat{d}_\beta & 0 \end{array}\right) \in \mathbb{R}^{2D\times 2D}$$

is the standard symplectic matrix. $S$ denotes the classical action integral

$$S(t, z) = \int_0^t \left[\frac{1}{2}\dot{q}(r) \cdot \dot{p}(r) - V(z(r))\right] dr$$

which solves the initial value problem

$$\dot{z}(t) = T(p(t)) - V(q(t)).$$

for all $z = (q, p) \in \mathbb{R}^{2D}$. In (9), the Herman–Kluk prefactor

$$R(t, z) = 2^{-D/2} \det(M_{\alpha\beta} + y^1 \cdot M_{y\beta} \cdot y - iM_{y\beta} \cdot y + iy^1 \cdot M_{y\beta})^{1/2}$$

depends on the matrices

$$M_{\alpha\beta} = \partial_\alpha \partial_\beta \in \mathbb{R}^{D\times D} \quad (\alpha, \beta \in [q, p]),$$

i.e., the four $D \times D$ block components of the $2D \times 2D$ stability matrix $M$. Stability matrix, defined as the Jacobian $M(t) = \partial z(t)/\partial z$ of the flow map, is the solution to the variational equation

$$M(t) = J \cdot \text{Hess} h(z(t)) \cdot M(t), \quad M(0) = \text{Id}_{2D},$$

with Hess $h$ the Hessian of the Hamiltonian function $h$.

The Herman–Kluk approximation (9) has been mathematically justified in different works [53, 56–58]. It has been shown that the exactly evolved quantum state is approximated by the Herman–Kluk state (9) with an error of the order of $h$. More precisely,

$$\sup_{t \in [0, T]} |||\psi(t)\rangle - |\psi_{\text{HK}}(t)\rangle||_2 \leq C(T)h,$$

for all initial data $|\psi_0\rangle$ of norm one, where $T > 0$ is a fixed time and $C(T) > 0$ is a constant independent of $h$ and independent of $|\psi_0\rangle$. If the potential is at most quadratic, then the approximation is exact [53]. For the expectation value of an observable $A$, the error of the Herman–Kluk approximation can be pessimistically estimated as

$$\langle \psi(t)| \hat{A}|\psi(t)\rangle = \langle \psi_{\text{HK}}(t)|\hat{A}|\psi_{\text{HK}}(t)\rangle + O(h),$$

by using the triangle inequality. In particular, this gives an upper bound for the error of the squared norm (if $\hat{A} = \hat{I}$) or energy (if $\hat{A} = \hat{H}$). However, this coarse estimate is potentially not sharp, since it cannot account for error cancellation due to oscillation.

### 2.2 Discretisation

Evolving the wavefunction (9) with the Herman–Kluk propagator requires evaluating an integral over the phase space $\mathbb{R}^{2D}$ and the overlap of the initial state with a frozen Gaussian. Furthermore, the algorithm needs to propagate the trajectories $z(t) = (q(t), p(t))$, the classical action $S(t, z)$, and the Herman–Kluk prefactor $R(t, z)$ according to Hamilton’s equations of motion for all chosen quadrature points $z \in \mathbb{R}^{2D}$. The latter can be achieved using symplectic integration methods to preserve also the symplectic structure of the classical Hamiltonian system. Due to the curse of dimensionality, for high $D$ the integral on $\mathbb{R}^{2D}$ must be evaluated using mesh-free discretization, such as Monte Carlo methods [59].
To evaluate the Herman–Kluk wavefunction (9) by Monte Carlo sampling, we rewrite the integral from Eq. 9 as
\[
|\psi_{HK}^N(t)\rangle = \langle r(z) | \phi(t, z) \rangle_{\rho_{\mu N}}^N \tag{19}
\]
where we introduced the notation
\[
\langle \psi(t, z) \rangle_{\rho_{\mu N}} := \int_{\mathbb{R}^D} \psi(t, z) \, d\mu = \int_{\mathbb{R}^D} \psi(t, z) \rho(z) \, d\nu \tag{20}
\]
for the phase-space average of \(|\psi(t, z)\rangle\) with respect to a probability measure \(\mu\) with density \(\rho(z) = d\mu/d\nu\) and defined a time-dependent state
\[
|\phi(t, z)\rangle := R(t, z)e^{iS(t,z)/\hbar} |g_{\zeta(z)}^z\rangle, \tag{21}
\]
i.e., a propagated frozen Gaussian multiplied by the Herman–Kluk and phase prefactors, and a time-independent function
\[
r(z) := \langle g_j^z | \psi_t \rangle \rho(z)^{-1}. \tag{22}
\]
The Monte Carlo estimator is then given by
\[
|\psi_N(t)\rangle = \frac{1}{N} \sum_{j=1}^N |\psi(t, z_j)\rangle, \tag{23}
\]
where \(\psi(t, z_j)\) is the state obtained from initial condition \(z_1\) and \(z_2, \ldots, z_N\) are sampled from probability density \(\rho(z)\).

As for any importance sampling, there are infinitely many ways to decompose the time-independent part of the phase-space integrand in Eq. 9 into the product \(\langle g_j^z | \psi_t \rangle \rho(z)\) of a prefactor \(r\) with a normalized sampling density \(\rho\). If one computes observables and correlation functions, which are quadratic in the initial state, \(\rho(z)\) is typically taken to be the Husimi probability density
\[
\rho_{\mu}(z) := \langle g_j^z | \psi_t \rangle^2 \tag{24}
\]
of the initial state \(|\psi_t\rangle\). For Husimi distribution, the prefactor \(r(z)\) becomes
\[
r_{\mu}(z) = \langle \psi_t | g_j^z \rangle^{-1}. \tag{25}
\]
However, since the wavefunction evolved with the Herman–Kluk propagator is first- and not second-order in \(|\psi_t\rangle\), it is natural to also test the square root of the Husimi density and to consider the probability density
\[
\tilde{\rho}(z) := \frac{\langle g_j^z | \psi_t \rangle}{\int_{\mathbb{R}^D} \langle g_j^z | \psi_t \rangle \, d\nu} \tag{26}
\]
with a bounded prefactor
\[
\tilde{r}(z) := \langle g_j^z | \psi_t \rangle \tilde{\rho}(z)^{-1}. \tag{27}
\]
Indeed, in their early paper [8], Kluk et al. used this “square-root” approach for computing the Herman–Kluk wavefunction and mentioned that it was “especially appealing because it [was] a well defined, non-arbitrary way of choosing the basis […]” In the following, we shall show that the square-root approach is indeed optimal, but the number of samples still suffers from an exponential dependence on the dimension.

The two probability densities \(\rho_{\mu}(z)\) and \(\tilde{\rho}(z)\) can now be used to compute the phase-space integral by Monte Carlo integration. To sum up, we have two cases, in which we evaluate \(|\psi_{HK}^N(t)\rangle\) either as
\[
|\psi_{HK}^N(t)\rangle = \langle r_{\mu}(z) | \phi(t, z) \rangle_{\rho_{\mu N}}^N \tag{Case H}
\]
or as
\[
|\psi_{HK}^N(t)\rangle = \langle \tilde{r}(z) | \phi(t, z) \rangle_{\rho_{\mu N}}^N \tag{Case sqrt – H}
\]
In general, the integral over \(\mathbb{R}^D\) defining the overlap of the initial wavefunction with a Gaussian has to be computed by numerical quadrature. However, for important specific cases analytical formulas are available. If the initial wavefunction is a Gaussian wavepacket \(|\psi_{\mu}\rangle = |g_{\zeta(0)}^z\rangle\) centred at some phase-space point \(z_0 = (q_0, p_0) \in \mathbb{R}^{2D}\), then
\[
\langle g_j^z | \psi_{\mu} \rangle_{\mathbb{R}^D} \equiv \exp \left[ \frac{-1}{2\hbar} (z - z_0)^T \cdot \Sigma_0 \cdot (z - z_0) \right] \cdot \exp \left[ \frac{i}{2\hbar} (p + p_0)^T \cdot (q - q_0) \right], \tag{28}
\]
where \(\Sigma_0 := \begin{pmatrix} \gamma & 0 \\ 0 & \gamma^{-1} \end{pmatrix}\) is the matrix containing the width parameters of the initial coherent state. Then, the Husimi density is given by
\[
\rho_{\mu}(z) = \exp \left[ \frac{-1}{2\hbar} (z - z_0)^T \cdot \Sigma_0 \cdot (z - z_0) \right], \tag{29}
\]
whereas the second approach provides the density
\[
\tilde{\rho}(z) = 2^{D/2} \exp \left[ \frac{-1}{4\hbar} (z - z_0)^T \cdot \Sigma_0 \cdot (z - z_0) \right] \tag{30}
\]
and prefactor
\[
\tilde{r}(z) = 2^D \exp \left[ \frac{i}{2\hbar} (p + p_0)^T \cdot (q - q_0) \right]. \tag{31}
\]

2.3 Summary of the numerical algorithm

Taking into account all the previous considerations, we slightly extend the natural numerical algorithm (described, e.g., Section 4 of Ref. [52]) for finding the Herman–Kluk approximation to the wavefunction at time \(t\).

Algorithm 1: (Herman–Kluk propagation)

1. Draw independent samples \(z_1, \ldots, z_N \in \mathbb{R}^{2D}\) from a distribution with density \(\rho_{\mu}(z)\) or \(\tilde{\rho}(z)\) given by Eqs. 29 and 30.
2. For all \(j \in \{0, 1, \ldots, N\}:
   2.1 Set initial values \(z(0) = z_j, M(0) = \text{Id}_{2D}\), and \(S(0) = 0\).
   2.2 Compute approximate solutions to Eqs. 10, 13 and 16 up to time \(t\) with a symplectic integration method [60] based on the Störmer–Verlet scheme [61, 62].
   2.3 Compute the Herman–Kluk prefactor \(R(t, z_j)\) from \(M(t)\) while choosing the correct branch of the complex square root [63], which guarantees continuity of \(R(t, z)\) as a function of \(t\).
3. Calculate \(|\psi_N(t)\rangle\) by means of formula (23) with \(|\psi(t, z_j)\rangle\) replaced with either
\[
|\psi_{HK}^N(t)\rangle = r_{\mu}(z_j) R(t, z_j) e^{iS(t,z_j)} \langle g_j^z | \phi(t, z_j) \rangle_{\rho_{\mu N}}^N \tag{32}
\]
or
\[
|\psi_{HK}^N(t)\rangle = \tilde{r}(z_j) R(t, z_j) e^{iS(t,z_j)} \langle g_j^z | \phi(t, z_j) \rangle_{\rho_{\mu N}}^N \tag{33}
\]
where \( r_H(z) \) and \( \tilde{r}(z) \) are given by Eqs. 25, 28 and 31.

We note that Eqs. 10, 13 and 16 can be evaluated simultaneously with a single numerical integrator. To increase the accuracy of the time integration one can use higher-order composition methods [64, 65]. They increase the order of the time integrator, but also its numerical cost. A higher-order time integrator is not necessarily useful since the phase-space error occurring from the Monte Carlo quadrature usually dominates the time integration error.

### 3 Phase space error analysis

Algorithm 1 relies on the discretisation of the phase-space integrals and of the system of ordinary differential equations. Here we focus only on the phase-space discretisation error. A similar, but less formal phase-space error analysis was applied to various algorithms for computing fidelity and classical correlation functions [66–69].

#### 3.1 Moments of the integrand

To assess the accuracy of the Monte Carlo estimator (23), we examine the moments of the two different integrands: \( |\psi_t(t)\rangle \) and \( |\tilde{\psi}(t)\rangle \). First, we observe that for any \( s > 0 \),

\[
E\{|\tilde{\psi}(t)|^s\} = \int_{\mathbb{R}^d} |\tilde{\psi}(t)|^s \, d\tilde{\mu}(\tilde{z}) < \infty, \tag{34}
\]

since \( \tilde{\psi}(t) \) and the Herman–Kluk prefactor \( R(t, z) \) are both bounded functions. For a discussion of the boundedness of \( R(t, z) \), see Section 1 of the Supplementary Material. In contrast,

\[
E\{|\psi(t)|^s\} = \int_{\mathbb{R}^d} |\psi(t)|^s \, \tilde{\mu}_H(z) = \int_{\mathbb{R}^d} |\psi(t)|^s \, |g^{\psi}_t||\psi_t\rangle^\dagger \, \Sigma \, \tilde{\mu}_H(z) \tag{35}
\]

ceases to be finite for \( s \geq 2 \). However, both integrands have a finite first moment, so that the strong law of large numbers (Theorem 2.4.1 in Ref. [70]) provides convergence of the estimator,

\[
|\psi_N(t)\rangle \rightarrow |\psi^{HK}(t)\rangle \quad \text{as} \quad N \rightarrow \infty, \tag{36}
\]

with probability one. Divergence of the second moment for (Case H) does not violate convergence of the estimator, but results in a slightly worse convergence rate than the one for (Case sqrt-H). Numerical results in Section 4 confirm this expectation. This shows that the initial sampling density has to be chosen carefully.

#### 3.2 Mean squared error

For (Case sqrt-H) the second moment is finite, so that the mean squared error of the Monte Carlo estimator (23) is well-defined and satisfies

\[
E\{|\psi_N(t)\rangle - |\psi^{HK}(t)\rangle|^2\} = \frac{V[|\tilde{\psi}(t)\rangle]}{N}, \tag{37}
\]

where the expectation value and the variance are with respect to the density \( \tilde{\rho}(z) \). Moreover (see also [52]),

\[
V[|\tilde{\psi}(t)\rangle] = \int_{\mathbb{R}^d} |\tilde{\psi}(t)\rangle - E[|\tilde{\psi}(t)\rangle]|^2 \tilde{\mu}(z) = \int_{\mathbb{R}^d} |R(t, z)|^2 |\tilde{r}(z)|^2 \tilde{\mu}(z) - ||\psi^{HK}(t)\rangle||^2. \tag{38}
\]

In the special case of an initial Gaussian initial wavepacket \( |\psi_0\rangle = |g^{\psi}_0\rangle \), this simplifies to

\[
V[|\tilde{\psi}(t)\rangle] = 4\int_{\mathbb{R}^d} |R(t, z)|^2 \tilde{\mu}(z) - ||\psi^{HK}(t)\rangle||^2, \tag{39}
\]

and at initial time \( t = 0 \) we obtain

\[
V[|\tilde{\psi}(0)\rangle] = 4^2 - 1, \tag{40}
\]

since the Herman–Kluk prefactor satisfies \( R(0, z) = 1 \).

For a more general assessment of the variance, numerical experiments in Section 4 consider the error between the approximations with \( N \) and \( 2N \) samples. By the linearity of the expectation value and the triangle inequality, this error can be estimated by

\[
E\{|\psi_N(t)\rangle - |\psi^{HK}(t)\rangle|^2\} \leq E\{|\psi_N(t)\rangle - |\psi^{HK}(t)\rangle|^2\} + E\{|\psi^{HK}(t)\rangle - |\psi_N(t)\rangle|^2\} \tag{41} 
\]

Note that Eq. 37 gives only the expected convergence error, i.e., the convergence error averaged over infinitely many independent simulations, each using \( N \) trajectories. The actual convergence error for any specific simulation with \( N \) trajectories may deviate from this analytical estimate substantially due to statistical noise. Nevertheless, in Section 2 of the Supplementary Material, we explain how Eq. 37 can also provide a rigorous lower bound and asymptotic estimate of the number of trajectories needed for convergence of a single simulation.

#### 3.3 Other sampling densities

For the special case of an initial Gaussian wavepacket \( |\psi_0\rangle = |g^{\psi}_0\rangle \), the two proposed sampling densities \( \rho_H(z) \) and \( \tilde{\rho}(z) \) belong to a family of normal distributions with probability density functions

\[
\rho_H(z) = \left( \frac{2}{a} \right)^D \exp\left[ -\frac{1}{a^2} \right], \tag{42}
\]

with \( a \geq 2 \). In the spirit of importance sampling, the Herman–Kluk wavefunction can accordingly be written as a phase-space average

\[
|\psi^{HK}(t)\rangle = \langle |\psi_x(t, z)\rangle \rangle_{\rho_H(\cdot, \cdot)} \tag{43}
\]

At time \( t = 0 \), the norm of the integrand satisfies

\[
||\psi_x(0, z)|| = \left( \frac{a}{3} \right)^D \exp\left[ -\frac{a - 4}{4a^2} (z - z_0)^2 \cdot \Sigma \cdot (z - z_0) \right], \tag{44}
\]

which implies for the variance

\[
V[|\psi_x(0)\rangle] = \left( \frac{a}{4\pi^D} \right)^D \int_{\mathbb{R}^d} \exp\left[ -\frac{a - 2}{2a} |z|^2 \right] dz - 1 \tag{45}
\]

For \( a > 2 \), the function \( a - 2a^2/2(2a - 4) \) attains its minimum at \( a = 4 \), which corresponds to the sampling density \( \tilde{\rho} \). In other words,
(Case sqrt-H) is optimal as far as the mean squared error is concerned. Nevertheless, even this optimal sampling results in an unfavorable exponential growth with the number of dimensions $D$.

### 3.4 Harmonic motion

The one-dimensional harmonic oscillator

$$\hat{H} = -\hbar^2 \frac{d^2}{2m dx^2} + \frac{m \omega^2}{2} x^2$$

is one of the rare examples for which explicit expressions for the solution of the Schrödinger equation and for the Herman–Kluk prefactor exist. For an initial Gaussian wavepacket $|\psi_0\rangle = |g_{\zeta}^0\rangle$ with position and momentum $q_0, p_0 \in \mathbb{R}$, the exact wavefunction is given by [71]

$$\psi_\alpha(x, t) = \exp\left\{ \frac{i}{\hbar} \frac{\alpha_i}{2} (x - q_0)^2 + p_i (x - q_0) + \beta_i \right\},$$

where

$$\alpha_i = \frac{1}{b} \alpha_0 \cos(\omega t) - b \sin(\omega t) \frac{\beta_0}{b} \sin(\omega t),$$

$$q_i = q_0 \cos(\omega t) + \frac{p_0}{b} \sin(\omega t),$$

$$p_i = p_0 \cos(\omega t) - bq_0 \sin(\omega t) \text{ and}$$

$$\beta_i = \beta_0 + \frac{1}{b} \left[ q_i p_t - q_t p_i + i\hbar \ln\left( \frac{z_t}{\beta_0} \right) \right].$$

with the abbreviations $z_t = b \cos(\omega t) + \alpha_0 \sin(\omega t)$, $\alpha_0 = i\gamma$, and $b = \omega v$. Here, $\beta_0$ includes the normalization constant for the wavefunction at time $t = 0$. The classical action is given by

$$S(t, q_0, p_0) = \frac{1}{2} \sin(\omega t) \left[ \frac{p_t^2}{b} - b q_t^2 \right] \sin(\omega t) - q_t p_0 \sin(\omega t).$$

The four components of stability matrix $M$ can be obtained, from their definition (15), by differentiating expressions for $q_i$ and $p_i$ with respect to $q_0$ and $p_0$, namely,

$$M(t) = \begin{pmatrix} \cos(\omega t) & b^{-1} \sin(\omega t) \\ -b \sin(\omega t) & \cos(\omega t) \end{pmatrix}. \quad (53)$$

The Herman–Kluk prefactor satisfies

$$R(t) = \left( \frac{1}{2} \left[ 2 \cos \omega t - i \sin \omega t \left( \frac{\gamma}{b} + \frac{b}{\gamma} \right) \right] \right)^{1/2},$$

so that the variance (38) can be written as

$$\mathbb{V}[|\psi(t)|^2] = \left[ 4 \cos^2(\omega t) + \left( \gamma \frac{b}{\gamma} + \frac{b}{\gamma} \right)^2 \sin^2(\omega t) \right]^{1/2} - 1. \quad (55)$$

This implies that for (Case sqrt-H) applied to a harmonic oscillator, the mean squared error of our Monte Carlo estimator oscillates with a period of $\pi/\omega$ between

$$3 \leq \mathbb{V}[|\psi(t)|^2] \leq 2 \left( \frac{\gamma}{mb} + \frac{mb}{\gamma} \right) - 1. \quad (56)$$

### 4 Numerical examples

In this section, we complement our previous theoretical results with numerical examples. We start by examining how the performance of Algorithm 1 depends on the method to discretise the phase space. We explore the time dependence of the variance of the Monte Carlo estimator in one dimension in a harmonic oscillator as well as in a series of increasingly anharmonic Morse potentials. The Monte Carlo integration is tested by averaging over $N$ independent, identically distributed samples of initial conditions. We approximate its convergence rate by assuming a power law

$$F(N) = cN^{-s}.$$  \quad (57)

dependence of the mean statistical error on the number of samples $N$. The prefactor $c$ and order $s$ of convergence are determined by the linear fit (in the least-squares sense) of the logarithm of Eq. 57 to the dependence of the logarithm of the statistical error on the logarithm of $N$.

Throughout our numerical examples, we work in atomic units ($\hbar = 1$), mass-scaled coordinates and with an initial state that is a Gaussian wavepacket with phase-space centre $z_0 \in \mathbb{R}^{2D}$. 

![Figure 2](image-url)
4.1 Initial phase-space error

We start by considering a spherical initial Gaussian wavepacket $|\psi_{ex}(0)\rangle = |g\rangle^\gamma$ with a width parameter $\gamma = 2Id_0$ in one and four dimensions. For $D = 1$, it is centred at $z_0 = (-1, 0)$ and for $D = 4$, at $z_0 = (-1, 1, 1, 1, 0, 0, 0, 0)$. Figure 2 shows the $L^2$-distance

$$\|\psi_N(t) - \psi_{ex}(t)\|_2,$$

(58)

of the Monte Carlo estimators for (Case H) and (Case sqrt-H) from the exact wavefunction at initial time as a function of the number of Monte Carlo quadrature points. We can immediately see that the analytical prediction (40) of the mean squared error (37) of (Case sqrt-H) is fulilled. For (Case H), the curve-fitting approximation (57) provided $(c, s) = (2.56, -0.48)$ for $D = 1$ and $(c, s) = (19.3, -0.36)$ for $D = 4$. It shows that both cases converge to the correct result and that (Case sqrt-H) performs slightly better than (Case H). Additionally, Figure 3 displays the $L^2$-distance of the estimators for both cases from the exact wavefunction at initial time as a function of the dimension $D$. Each wavefunction was approximated with $N = 8 \cdot 10^3$ trajectories. The analytical prediction (40) for (Case sqrt-H) is realized. Moreover, the error for (Case H) increases faster with $D$.

4.2 Harmonic potential

To analyze the effect of dynamics on the convergence, let us consider a harmonic potential $V(x) = x^2/2$ in one dimension and explore the dynamics for one full oscillation period. The initial Gaussian wavepacket is still localized in $z_0 = (-1, 0)$ with width $\gamma = 2$. In Figure 4, we compare the exact wavefunction (47) with the numerical realization of the Herman–Kluk propagator which uses the exact solution to $q(t)$, $p(t)$, $S(t, z)$ and $R(t, z)$ stated in Eqs 49, 50, 52, 54. Since the Herman–Kluk propagator is exact for harmonic motion and since we supply exact classical trajectories, the observed numerical error is only due to the Monte Carlo integration. The upper panel of Figure 4 shows the time dependence of the $L^2$-error

$$\|\psi_N(t) - \psi_{ex}(t)\|_2,$$

(59)

where the semiclassical wavefunctions were generated using $N = 2^{16}$ trajectories. Sampling from the square root of the Husimi density (Case sqrt-H) results in approximately twice smaller error than sampling from the Husimi density itself. For (Case sqrt-H), the figure also displays the analytical error estimate derived in (55), which matches the numerical error up to small statistical noise. To remove this statistical noise and to match the analytical estimate (55) more accurately, in the lower panel of Figure 4 we plot the empirical root mean square error (RMSE) [59] $S_{100}$, where

$$S_K := \frac{1}{K} \sum_{j=1}^{K} \|\psi_N^{(j)}(t) - \psi_{ex}(t)\|_2^2,$$

(60)

$K$ is an integer number of independent simulations (indexed by $j$) and each $\psi_N^{(j)}$ was itself approximated using $N$ independent samples. One can see that

$$\mathbb{E}[S_K] = \mathbb{E}\left[\|\psi_N(t) - \psi_{ex}(t)\|_2^2\right] = \frac{\mathbb{V}[\psi(t)]}{N},$$

(61)

For $K = 1$, one obtains the result represented in the upper panel of Figure 4. For $K \to \infty$, due to the strong law of large numbers, $S_K$
converges almost surely to its expectation value and hence to the analytical error estimate.

The lower panel of Figure 4 shows the empirical RMSE computed with \( K = 100 \) and \( N = 2^{16} \). For (Case sqrt-H), it coincides almost perfectly with the analytical prediction. We note that the error reaches its maximum whenever the wavefunction passes through the bottom of the potential and its minimum when the wavefunction arrives at the turning points. Even though this analysis makes only sense for finite variance, the figure also displays the empirical RMSE for (Case H), which is nearly constant. Both panels show a qualitatively similar error evolution for (Case H), however, at a magnitude that is considerably larger than the error for (Case sqrt-H).

### 4.3 Morse potential

To investigate the convergence of the Herman–Kluk wavefunction in anharmonic systems, we consider dynamics generated by a less and more anharmonic Morse potentials. The parameters were taken from [29]. Our initial state is a Gaussian wavepacket with zero initial position and momentum \((q_0, p_0) = (0, 0)\), and with a width parameter \(y = 0.00456\) a.u. \(\approx 1000\) cm\(^{-1}\). The Morse potential

\[
V(x) = V_{\text{eq}} + D_x \left[ 1 - e^{-a(x-z_{\text{eq}})} \right]^2
\]

is characterized by the dissociation energy \(D_x\), decay parameter \(a\), and the position \(q_{\text{eq}}\) and energy \(V_{\text{eq}}\) of the minimum. We considered two Morse potentials, both with \(V_{\text{eq}} = 0.1\) and \(q_{\text{eq}} = 20.95\) a.u., but with different values of \(a\) and \(D_x\). The latter two parameters, however, were chosen so that the global harmonic potential fitted to the Morse potential at \(q_{\text{eq}}\) had the same frequency

\[
\omega_{\text{eq}} = \sqrt{V'(q_{\text{eq}})} = \sqrt{2D_xa^2} = 0.0041 \text{ a.u.} \approx 900 \text{ cm}^{-1}
\]

for the two Morse potentials. The anharmonicity of the potentials was conveniently controlled with the dimensionless parameter

\[
\chi = \frac{\hbar \omega_{\text{eq}}}{4D_x} \quad (62)
\]

which is also reflected in the bound energy levels [71]

\[
E_n = \hbar \omega_{\text{eq}} \left(n + \frac{1}{2}\right) - \chi \left(n + \frac{1}{2}\right)^2
\]

of a Morse oscillator. Then \(D_x\) and \(a\) are given by

\[
D_x = \frac{\hbar \omega_{\text{eq}}}{4V_{\text{eq}}}, \quad a = \sqrt{2\frac{\hbar \omega_{\text{eq}} \chi}{\hbar}}
\]

(66)

We choose two different values

\[\chi = 0.005 \quad \text{and} \quad \chi = 0.01\]

of anharmonicity and compare the Herman–Kluk propagation with a grid-based reference quantum calculation obtained by the Fourier-split method [72], which is second-order accurate with respect to the time step. The position grid was set from \(x = -200\) to 1500 with 4096 equidistant points for \(\chi = 0.005\) and from \(x = -200\) to 10,000 with 16,384 equidistant points for \(\chi = 0.01\). The larger grid for \(\chi = 0.01\) was required to capture oscillations of the wavefunctions in the tail region, which are due to the increased anharmonicity. For the time propagation of the Herman–Kluk wavefunction, we used a second order Störmer-Verlet scheme with step size \(\Delta t = 8\) a.u. \(\approx 0.194\) fs.

Because the Herman–Kluk approximation is not exact in a Morse potential, to separate the statistical convergence error from the semiclassical error of the fully converged Herman–Kluk approximation, in Figure 5 we show the \(L^2\)-error

\[
|\psi_N(t) - \psi_{2N}(t)|
\]

(68)

between the Herman–Kluk wavefunctions calculated with \(N\) and \(2N\) trajectories as a function of \(N\). Both wavefunctions were propagated in a Morse potential with anharmonicity \(\chi = 0.005\). Each panel includes the error for the fixed time \(t\) after approximately one oscillation (196 time steps) and ten oscillations (1960 time steps). In addition, the convergence rates for both sampling schemes were fitted to the same power law (57). We observe that sampling from the square root of the Husimi density (Case sqrt-H), shown in the lower panel, performs better than sampling from the Husimi density (Case H), displayed in the upper panel.

Figure 6 shows the analogous results obtained in a Morse potential with a larger anharmonicity parameter \(\chi = 0.01\). Here, we display the wavefunctions after 202 and 2020 time steps, which are approximately the times after the first and tenth oscillations. As expected for anharmonic evolution, the error after ten oscillations is worse than after one oscillation.
Increased anharmonicity also increases the error in comparison to Figure 5. Again, the sampling from the square root of the Husimi density (Case sqrt-H) has consistently a lower error than (Case H).

To complement the abstract convergence study of the $L^2$-error, in the upper panels of Figures 7 and 8, we compare the more intuitive position probability densities of the "exact" quantum grid-based solution with those of (Case H) and (Case sqrt-H). Both figures were obtained in a Morse potential with anharmonicity parameter $\chi = 0.01$ after 10 oscillations (2020 time steps $\approx 392$ fs). Position probability densities of the Herman–Kluk propagator for (Case H) and (Case sqrt-H) were computed with $N = 800$ trajectories.

### Table 1

Summary of convergence rates for (Case sqrt-H) and (Case H) at initial time, in a harmonic oscillator and in two Morse potentials after one and ten oscillations.

| Initial time | (Case sqrt-H) | (Case H) |
|--------------|---------------|----------|
| $D = 1$      | $\sqrt{(4D^2 - 1)} \cdot N^{-1/2}$ | $2.56 \cdot N^{-0.86}$ |
| $D = 4$      | $\sqrt{(4D^2 - 1)} \cdot N^{-1/2}$ | $19.3 \cdot N^{-0.86}$ |
| Harmonic potential | $\sqrt{\langle |\psi(t)|^2 \rangle} \cdot N^{-1/2}$ with variance from (55) | $2.19 \cdot N^{-0.86} \quad 2.14 \cdot N^{-0.86}$ |
| Morse pot. $\chi = 0.005$ | $4.68 \cdot N^{-0.86} \quad 3.24 \cdot N^{-0.86}$ |
| Morse pot. $\chi = 0.01$ | $3.35 \cdot N^{-0.86} \quad 3.57 \cdot N^{-0.86}$ |

### Figures

**Figure 6**

Same as Figure 5, except that the anharmonicity parameter of the Morse potential was increased to $\chi = 0.01$.

**Figure 7**

Position probability densities (upper panel) and their absolute errors (lower panel) in a Morse potential with $\chi = 0.01$ after 10 oscillations (2020 time steps $\approx 392$ fs). Position probability densities of the Herman–Kluk approximation for (Case H) and (Case sqrt-H) were computed with $N = 800$ trajectories.
\[ \sqrt{H}. \] The spectra in the upper panel were obtained by the Fourier transform of the wavepacket autocorrelation function; the Herman–Kluk autocorrelation function was computed by sampling from the Husimi density (Case H), because it gives the exact result (=1) at \( t = 0 \) regardless of the number of trajectories and, therefore, converges faster at short times.

5 Conclusion and outlook

We compared two different sampling strategies for evaluating the semiclassical wavefunction evolved with the Herman–Kluk propagator. For the initial phase-space sampling, we either used the Husimi density (Case H) or its square root (Case \( \sqrt{H} \)). We showed that the square root sampling produces a Monte Carlo integrand with finite second moment, while the Husimi sampling comes with an undesirable infinite second moment. The numerical experiments for the harmonic oscillator and two Morse oscillators with different extents of anharmonicity confirm that the infinite second moment results in a slower convergence of the Monte Carlo estimator. Therefore, we recommend the square root approach (Case \( \sqrt{H} \)) whenever the Herman–Kluk propagator is used directly for approximating the quantum-mechanical wavefunction and the \( L^2 \)-error of the wavefunction approximation is the relevant accuracy measure. However, we explicitly verified that at initial time the square root density’s second moment, even though it is finite, has an unfavorable, exponential dependence on the dimension, possibly leading to a large number of trajectories required for a reasonably accurate wavefunction.

Although the wavefunction is a central object in quantum mechanics, one is often interested directly in observables, which can be computed as expectation values. It is clearly inefficient to compute expectation values, such as energy or squared norm, with the Herman–Kluk propagator by computing the wave function first. A follow-up paper, in which an analysis similar to that presented here will be applied to the autocorrelation function as well as to the expectation values is in preparation. In particular, the approach to expectation values proposed in [52] will be analysed in detail. Our present analysis and sampling approaches could, in principle, help increase the efficiency of any Gaussian-based method, although it is difficult to predict the possible implications that the coupling between different Gaussians present in Gaussian basis methods [9, 10] might have for the choice of the optimal sampling density.

Data availability statement

The raw data supporting the conclusion of this article will be made available by the authors, without undue reservation.

Author contributions

All authors have contributed to the design and execution of the research and to the writing of the manuscript. FK performed all numerical calculations and prepared all figures.

Acknowledgments

The authors acknowledge financial support from the European Research Council (ERC) under the European Union’s Horizon 2020 Research and Innovation Programme (Grant Agreement No. 683069–MOLEQULE) and from the EPFL.

Conflict of interest

The authors declare that the research was conducted in the absence of any commercial or financial relationships that could be construed as a potential conflict of interest.
