Background: There is a noticeable difference in serologic immune status against tetanus among different age and social groups in various countries due to different national vaccination policies and methods.

Objectives: Considering that the immunization status of trauma patients against tetanus is not-known or uncertain and they may need to receive the vaccine and tetabulin, this study was conducted to determine the tetanus antibody levels in patients referred to the trauma emergency ward of Shahid Beheshti Hospital in Kashan City, Iran.

Patients and Methods: This cross-sectional study was performed on 204 trauma patients referred to the trauma emergency ward of Shahid Beheshti hospital in Kashan City, Iran, in 2014. After obtaining a written informed consent from the patients, a questionnaire consisted of demographic information and tetanus vaccination record was completed by the patients. Afterwards, 4-5 mL venous blood sample was taken from each patient and the tetanus antibody level (IgG) was measured using the enzyme-linked immunosorbent assay method. The tetanus antibody levels equal or more than 0.1 IU/mL were considered protective. Data were analyzed using chi-square test, independent t-test and one-way ANOVA with SPSS software version 16.

Results: From a total of 204 patients, 35 cases (16.7%) were females and 169 (83.2%) were males with the mean age of 40.9 ± 3.7 years. There was no statistically significant difference in the tetanus antibody levels between both sexes (P = 0.09). Moreover, there was no significant difference in immunization status between the patients who had a history of tetanus vaccination and those who had not received the vaccine before (P = 0.67). The antibody levels were significantly reduced with the passage of time since the last vaccination (P < 0.001). Also, 87.3% of the patients had the high protective level of immunity to tetanus.

Conclusions: The findings of the present study show a high level of tetanus antibody among trauma patients in this hospital; so, taking the tetanus vaccine history can be misleading. It is suggested that further studies be performed in different regions of our country and with larger sample sizes and detection of the immunization status of patients by measuring anti-tetanus antibody levels among trauma patients is recommended to make suitable policy for a national vaccine protocol in the future.

Keywords: Tetanus; Vaccination; Tetabulin; Trauma

1. Background

Tetanus (lockjaw) is an acute disease of the nervous system that is characterized by an acute hypertonia, generalized and severe muscle spams and autonomic nervous system disorders. This disease is caused by a strong protein toxin called Tetanospasmin, which is produced by the anaerobic bacterium Clostridium tetani in a contaminated wound (1, 2). Tetanus disease can be prevented through proper immunization with the tetanus vaccine. Clostridium tetani is a Gram-positive, spore-forming anaerobic bacillus that is ubiquitous, being found throughout the world in the soil and in human and animal intestines (about 10% of the cases). The spores are very resistant to many environmental factors, such as heat and usual antisepsics and can stay dormant for a very long time. Tetanus bacilli are found throughout the world and more prevalent in rural areas and in warm climates during summer and also in individuals whose immunization status is uncertain or incomplete. Approximately, 1,000,000 tetanus-related deaths were reported in 1980. However, the death rate related to tetanus in 2006 was reported 290,000 deaths (3-6).

There is a significant difference in serologic immune status against tetanus among different age and social groups in various countries due to different national vaccination policies and methods. A wide range of protective immunity against tetanus has been reported in different studies (7-13). In the Razaghi et al. (14) study conducted in Kashan in 2008, 35% of the participants older than 59 years had the protective level of tetanus antibody.

In Hatamabadi et al. (15) study carried out on trauma pa-
tients referred to emergency ward of Imam Hossein Hospital in Tehran, 80.5% of the patients had a protective level of tetanus antibody. In Dominguez et al. study in Spain in 2007, the tetanus immunity level was 99.4% in adolescents and 68.3% in adults (16). The results of Khetsuriani et al. (17) study in Tajikistan showed that the total immunity against tetanus among children and adolescents was 78.9%, and the 10 - 19 year age group had the lowest immunity. The findings of the Kurtoglu et al. study (2000 - 2001) conducted on 2465 individuals with the age range of equal or more than 6 months showed that 73.5% of the cases had complete immunity against tetanus (18). Several studies showed that the antibody response to tetanus was different in terms of age and vaccination history (19-22).

2. Objectives
Considering that the immunization status of trauma patients against tetanus is uncertain, and these patients may need to receive the required vaccine and tetabulin, the purpose of this study was to determine the level of tetanus antibody in trauma patients referred to the trauma emergency ward of Shahid Beheshti Hospital in Kashan, and also to evaluate the efficiency of the national protocol in preventing tetanus.

3. Patients and Methods
This cross-sectional study was performed on 204 trauma patients referred to the trauma emergency department of Shahid Beheshti Hospital in Kashan City, Iran, in 2014. It was postulated that the prevalence of protective immunity against tetanus in Kashan was 35% based on the report by Razaghi et al. (14). Using the formula for estimating sample size, 204 cases were calculated as the minimum number of participants. The patients who did not consent to fill out the questionnaire were excluded from the study. The written informed consent was obtained from the patients or their family and then the participants were asked to complete a questionnaire including demographic information and tetanus vaccination records. Then, 4 - 5 mL venous blood sample was taken from the patients to perform the routine experiments and the patient’s blood serum was isolated immediately and the tetanus antibody level (IgG) was measured using the Enzyme-Linked Immunosorbent Assay (ELISA) method with the IBL kit (IBL, Hamburg, Germany) and an ELISA reader machine. Based on the instructions of the IBL kit and other similar studies, the antibody levels equal or more than 0.1 were considered as optimal protective levels and the antibody levels of 0.011 - 0.099 IU/mL were considered as low and weak immunity (23-25).

This study was approved by the ethics committee of Khashan University of Medical Sciences with the approval number 1833 (date: 25/4/93).

3.1. Data Analysis
Data were collected, statistical tables were prepared and the descriptive indices of central tendency and dispersion were also measured. Data were analyzed using chi-square, Independent t-test, one-way ANOVA and descriptive statistics with SPSS software version 16 (SPSS Inc., Chicago Illinois, USA).

4. Results
In this study, the tetanus antibody levels of trauma patients were measured. From a total of 204 patients, 35 cases (16.7%) were females and 169 (83.2%) were males with the mean age of 40.9 ± 3.7 years. Of 204 patients, 26 cases (12.7%) had low levels of immunity and 178 cases (87.3%) had high levels of immunity to tetanus. The results of the present study showed that the mean tetanus antibody level (± SD) in male patients was 2.21 ± 2.15 and in females was 1.15 ± 1.7, which no significant difference was observed in the antibody level between males and females in this hospital (P = 0.09).

Table 1 shows the tetanus vaccination history and duration in trauma patients. The protective tetanus antibody level was reduced with the passage of time from the last vaccination (P < 0.001).

Table 2 shows the immunity status of vaccination groups. Results of the current study showed that there was no significant difference in the immunity status among those who had a vaccination history and those who had not (P = 0.67).

### Table 1. Tetanus Vaccination History and Duration in Trauma Patients

| Vaccine History | No. (%) |
|-----------------|---------|
| Known duration, y |         |
| < 5             | 52 (25.4) |
| 5 - 10          | 16 (7.8)  |
| > 10            | 41 (20.4) |
| Total           | 109 (53.6) |
| Not-remember    | 82 (40.1) |
| No previous vaccination | 13 (6.3) |

### Table 2. Immunity Status of Vaccination Groups

| Vaccination Status | No. (%) |
|--------------------|---------|
| Vaccination        |         |
| Nonimmune          | 7 (16)  |
| Immune             | 37 (84) |
| Vaccination + Tetabulin |     |
| Nonimmune          | 13 (11.2)|
| Immune             | 103 (88.8) |
| None               |         |
| Nonimmune          | 6 (13.6) |
| Immune             | 38 (86.4) |
5. Discussion

This study was performed to measure the tetanus antibody level in trauma patients in Kashan City, Iran, in 2014. From a total of 204 trauma patients under the study, 35 cases (16.7%) were males and 169 (83.2%) were females with the mean age of 40.9 ± 3.7. The findings of this study revealed that the percentage of men referred to hospital due to trauma accidents is more than women and the trauma incidence in men is higher than women because men work more hours outside of the home and are at higher risk of trauma compared to women. The trauma incidence rates among men and women are in accordance with the national incidence of trauma injuries with hospitalization reported in Demographic and Health Survey in 1379 in which the incidence of trauma in men was more than three times higher than in women. In addition, the mean age of trauma patients (40.9 ± 3.7) in this study was in agreement with the national rate of mortality and inability due to trauma and shows that the selected samples, regarding their age and sex, are the appropriate samples of the population and thus can be generalized to a larger population (15). In this study, among 204 trauma patients, 26 cases (12.7%) were not immune and 178 (87.3%) had a high level of antibody and protective level of immunity. Results of the present study showed that no significant difference was observed in vaccination status between those who had received the tetanus vaccine and those who had not (P = 0.67).

The results of a study conducted by Razaghi et al. to study the immunity status against tetanus in individuals older than 50 years in Kashan showed that the protective immunity level in patients with a history of vaccination was 57.7% and in those with no history of vaccination was 18.1%, which this finding is in accordance with the finding of our study (14).

The results of the study conducted by Cassell et al. (26) in England (2002) to determine the tetanus immunization status in 269 burn patients under plastic surgery with the age range of 1-75 years showed that the rate of men was more than women; 200 patients had a history of vaccination, 31 cases had not received any vaccine and 38 cases were not sure whether they were vaccinated before or not. Also, results showed that the antibody level in patients who had received vaccine was significantly higher than the other patients, which is inconsistency with the results of our study (our study indicated that there was no difference with P = 0.67). The results of the Savage EJ et al. study (2007) with the title of "Audit of tetanus prevention knowledge and practices in accident and emergency departments in England" showed that 46.2% of the patients (the majority of them) expressed that they had received the tetanus vaccine more than 10 years ago. However, no significant difference was found in tetanus antibody level among the different groups with different vaccination history; this finding is different from that of our study (27). The results of the current study showed that there was no significant difference in tetanus antibody level between male and female patients in Kashan City. A study conducted by Wu CJ et al. (2009) to study the tetanus immunity level in Taiwan showed that the protective immunity level in men (73%) was higher than in women (49%) (28); this finding is incongruent with that of our study, and the difference was statistically significant. In a study conducted by Gergen PJ et al. (1995), which is a population-based serologic survey of immunity to tetanus in the United States showed that the immunity level in men (79%) was higher than in women (62.4%) (30); this finding is not in accordance with that of our study. Razaghi et al. (2011) carried out a study about the tetanus immunization status in individuals older than 50 years in Kashan and pointed out that the immunity level in men (43.7%) was higher than in women (27.9%); this finding is also in accordance with those of the previous studies and unlike our study the difference was statistically significant (14).

This higher level of immunity against tetanus in men can be due to the higher prevalence rate of road-traffic accidents among men than in women and men with trauma receive tetanus booster at the time of the accident (29). Also, men receive tetanus vaccine during military service in Iran and because of this men can have higher immunity against tetanus compared to women. The results of the present study showed that 21.5% of the trauma patients had received only tetanus vaccine, 57.1% had received both tetanus vaccine and tetabulin and 21.4% had received neither vaccine nor tetabulin. The results of the study conducted by Cassell et al. in England (2002) to determine the tetanus immunization status in 269 burn patients under plastic surgery showed that from a total of 49 patients under the study, 23 cases had received the tetanus vaccine, 17 cases had received both the vaccine and tetabulin and the remainder had received neither vaccine nor tetabulin (26), which is in accordance with the results of our study. A study conducted by Frink M et al. (2006) on tetanus vaccination in the accident and emergency department in Germany reported that from a total of 155 patients, 51% had received vaccine, 44% had received both vaccine and tetabulin and the remainder had received neither vaccine nor tetabulin (30), which its results are consistent with our results.

In conclusion, since in this study the tetanus antibody levels in three groups of patients, those who had received the vaccine, both the vaccine and tetabulin and neither the vaccine nor tetabulin, based on the national vaccination protocol are similar, this protocol has some weaknesses regarding the tetanus prevention and will need to be reviewed and updated. Since several studies showed that a rapid blood test, tetanus quick stick (TQS), could be helpful in assessing the immunity against tetanus, this test can be used in primary evaluation of trauma patients (31). Also, considering the high levels of tetanus antibody among trauma patients in this study.
and dropping of the antibody level with the passage of time from the last vaccination, it is recommended that the national vaccination schedule be carried out persistently in children and they received tetanus boosters every 10 years. Moreover, more researches with larger sample sizes should be performed and in case of obtaining similar results, the national protocol for management of the wounds be established.

Acknowledgments

We would like to thank the laboratory and emergency ward personnel of Shahid Beheshti Hospital in Kashan, Iran.
