(March 31, 2022)

We give an explicit expression for the entanglement of formation for isotropic density matrices in arbitrary dimensions in terms of the convex hull of a simple function. For two qubit isotropic states we determine the convex hull and we have strong evidence for its exact form for arbitrary dimension. Unlike for two qubits, the entanglement of formation for two qutrits or more is found to be a nonanalytic function of the maximally entangled fraction in the regime where the density matrix is entangled.

One of the main goals in quantum information theory is to develop a theory of entanglement. A cornerstone of this theory will be a good measure of bipartite entanglement. Such a measure must obey the essential property that the entanglement of a bipartite density matrix \(\rho\) which is shared by Alice and Bob cannot increase, on average, under local quantum operations and classical communication \((LO + CC)\) between Alice and Bob. In this way, the entanglement captures the truly quantum correlations in a bipartite density matrix. For pure bipartite states a good measure of entanglement has been found, it is the following quantity:

\[
E(\ket{\psi}\bra{\psi}) = S(\text{Tr}_B(\ket{\psi}\bra{\psi})),
\]

where \(S(\rho)\) is the von Neumann entropy of \(\rho\), i.e. \(S(\rho) = -\text{Tr} \log \rho\) and \(\text{Tr}_B(\ket{\psi}\bra{\psi})\) is the reduced density matrix that we obtain by tracing out Bob’s quantum system. This measure \(E\) is unique \(\cite{1,2}\) if one requires the entanglement to obey a set of natural properties, such as convexity, non-increase under local measurements, asymptotic continuity, partial additivity and normalization. Moreover, \(E\) is a measure of the asymptotic entanglement costs \(\cite{3}\) of making the state \(\ket{\psi}\) out of a canonical set of states, which we can choose to be EPR singlets \(\frac{1}{\sqrt{2}}(\ket{01} - \ket{10})\), which have \(E = 1\). This process is reversible, in the sense that one can concentrate a set of \(n\) states \(\ket{\psi}\) with entanglement \(E\) to a smaller set \(m = En\) EPR singlets.

The situation for mixed states is much more complex. In Ref. \(\cite{4}\) a first measure of mixed state entanglement, called the entanglement of formation, was introduced. This measure is a candidate for measuring the asymptotic costs of making the density matrix out of a supply of EPR singlets. There are no mixed density matrices for which this statement has been proved, but neither have counterexamples been found so far. The search for a possible discrepancy between the entanglement of formation and the asymptotic entanglement costs is hampered by the fact that we know the entanglement of formation only for two qubit systems; Wootters \(\cite{5}\) found an analytic expression for the entanglement of formation for all two qubit density matrices.

In this Letter we present the first calculation of the entanglement of formation of a class of density matrices in dimensions higher than \(\mathbb{C}^2 \otimes \mathbb{C}^2\). We explicitly determine the entanglement of formation for two qutrit density matrices in this class and we find an expression in arbitrary dimension in terms of the convex hull of a simple function. We conjecture the explicit form of this convex hull, which can be easily verified in a given dimension. Surprisingly, the entanglement of formation is found to be a nonanalytic function of the parameter characterizing the class of states that we consider.

Let us start by recalling the definition of the entanglement of formation. Let \(E_\rho = \{p_i, \ket{\psi_i}\}\) be an ensemble of pure states which form a decomposition of \(\rho = \sum_i p_i \ket{\psi_i}\bra{\psi_i}\). The entanglement of formation for mixed states \(\rho\) is defined as

\[
E(\rho) = \min_{E(\rho_i)} \sum_i p_i E(\ket{\psi_i}\bra{\psi_i}).
\]

In this Letter we will consider the class of density matrices, sometimes called isotropic density matrices, which are convex mixtures of a maximally entangled state and the maximally mixed state:

\[
\rho_F = \frac{1 - F}{d^2 - 1} (1 - |\Psi^+\rangle\langle\Psi^+|) + F |\Psi^+\rangle\langle\Psi^+|,
\]

for \(0 \leq F \leq 1\) and \(|\Psi^+\rangle = \frac{1}{\sqrt{d}} \sum_{i=1}^d |ii\rangle\). For \(F \leq 1/d\) these density matrices are separable \(\cite{6}\). The entanglement of formation for states with \(d = 2\) is equal to

\[
H_2(\mu), \quad \mu = \frac{1}{2} + \sqrt{F(1 - F)},
\]

where \(H_2(.)\) is the binary entropy function. The states \(\rho_F\) have the important property \(\cite{6}\) that they are invariant under the operation \(U \otimes U^*\) for any unitary transformation \(U\). The \(LO + CC\) “twirling” superoperator \(S^{U \otimes U^*}\) is defined as...
\[ S^U \otimes U^* (\rho) = \frac{1}{Vol(U)} \int \ dU \ U \otimes U^* \rho U^\dagger \otimes U^{\dagger}. \] (5)

In Ref. [8] the Schmidt number of the isotropic states was determined. Instead of making an isotropic state out of a set of maximally entangled states, we ask how to construct an isotropic state with a given \( F \) out of some state characterized by a Schmidt vector \( \vec{\mu} \). So, let us take an arbitrary initial pure state \( |\psi\rangle = \sum_{i=1}^d \sqrt{\mu_i} |a_i, b_i\rangle \) and consider the effect of twirling. We can write \( |\psi\rangle = U_A \otimes U_B \sum_i \sqrt{\mu_i} |i, i\rangle \) and thus

\[
S^U \otimes U^* \left( \sum_{i,j} \sqrt{\mu_i \mu_j} |a_i, b_i\rangle \langle a_j, b_j| \right) =
\]

\[
S^U \otimes U^* \left( (1 \otimes V) \sum_{i,j} \sqrt{\mu_i \mu_j} |i, i\rangle \langle j, j| (1 \otimes V^\dagger) \right),
\] (6)

where \( V = U_A^\dagger U_B \). We define \( v_{ij} = \langle i | V | j \rangle \). The twirled state becomes

\[
S^U \otimes U^* (|\psi\rangle \langle \psi|) = \left[ \sum_i \nu_i^2 \right] P_+ + \frac{1 - \left| \sum_i \nu_i^2 \right|}{d^2 - 1} (1 - P_+),
\] (7)

where \( \nu_i = \sqrt{\mu_i} v_{ii} \) and \( P_+ = \langle |\Psi^+\rangle \langle \Psi^+| \rangle \). When we choose \( V = 1 \) we find the density matrix \( \rho_F \) at \( F = \left[ \sum_i \sqrt{\mu_i}^2 \right]/d \). For general \( V \) one can bound

\[
\left| \sum_i \nu_i^2 \right| \leq \left( \sum_i |\nu_i|^2 \right) \leq \left( \sum_i \sqrt{\mu_i}^2 \right),
\] (8)

since \( |v_{ii}| \leq 1 \) for all \( i \). Thus the largest value for \( F \) is obtained by choosing the initial state \( \sum_{i=1}^d \sqrt{\mu_i} |i, i\rangle \).

The use of symmetry makes it possible to give a simplified expression for the entanglement of formation for isotropic states:

**Lemma 1** The entanglement of formation for isotropic states in \( \mathbb{C}^d \otimes \mathbb{C}^d \) \((d \geq 2)\) for \( F \in (1/d, 1] \) is given by

\[ E(\rho_F) = co(R(F)), \] (9)

where \( co(g) \) denotes the convex hull of the function \( g \) and \( R(F) \) is defined as

\[ R(F) = \min_{\vec{\mu}} \left\{ H(\vec{\mu}) | F = \left( \sum_{i=1}^d \sqrt{\mu_i}^2 \right)/d \right\}, \] (10)

and \( \vec{\mu} \) is a Schmidt vector.

**Proof** Assume that there exists an optimal decomposition of \( \rho_F \) formed by the ensemble \( \{p_i, |\psi_i\rangle \langle \psi_i| \} \), where \( \vec{\mu} \) denotes the Schmidt vector of the state \( |\psi_i\rangle \). By twirling the l.h.s. and r.h.s. of the equation \( \rho_F = \sum_i p_i |\psi_i\rangle \langle \psi_i| \) we obtain that \( \rho_F = \sum_i p_i \rho_{F_i} = \rho \sum_i p_i F_i \), where

\[ F_i(V_i, \vec{\mu}) = \frac{\left| \sum_k v_{kk} \sqrt{\mu_k} \right|^2}{d}, \] (11)

as in Eq. (7). Since the decomposition is optimal, each Schmidt vector \( \vec{\mu} \) has minimal entropy under this constraint. Consider the function

\[ R_V(F) = \min_{\vec{\mu}} \left\{ H(\vec{\mu}) | F = \left( \sum_{i=1}^d v_i \sqrt{\mu_i} \right)/d \right\}. \] (12)

An optimal decomposition of \( \rho_F \) is a convex combination of pure states each of which corresponds to a certain \( F \) under twirling. Thus the entanglement of formation \( E(\rho_F) \) can be obtained by taking the convex hull of the functions \( co(R_V(F)) \). We can make an additional simplification. Eq. [8] implies that \( R_V(F) = R(\rho_F) \equiv R(F') \) where \( F' \geq F \) for every \( V \). Thus instead of taking the convex hull of all functions \( co(R_V(F)) \), we can take the convex hull of function \( R_+(F) = \min_x \{ R(x) | x \geq F \} \). In Lemma 2 we will determine \( R(F) \) and it is not hard to show that \( R(F) \) is a monotonically increasing function of \( F \). It follows then that \( R_+(F) = R(F) \) and \( co(R_+(F)) = co(R(F)) \). \( \square \)

We now determine the function \( R(F) \) defined in Eq. (10). Since all the equations are symmetric in \( \mu_i \), we can restrict ourselves to solutions which satisfy \( \mu_1 \geq \mu_2 \geq \ldots \geq \mu_d \). With the method of Lagrange multipliers we get a necessary condition for the minimum

\[ -1 - \log \mu_i + \frac{A_1}{2} \mu_i \frac{\pm}{\mp} = 0, \] (13)

where \( A_1, A_2 \) denote the Lagrange multipliers. For fixed \( A_1, A_2 \) this determines the whole set \( \{\mu_i\} \). Setting \( \mu_i = \frac{1}{q^2} \) we obtain an expression of the form \( \log q_i = A_i + B \) where \( A, B \) only depend on \( A_1, A_2 \). Since a convex and a concave function cross each other in at most two points, this equation has maximally two possible nonzero solutions for \( q_i \). Therefore all Schmidt vectors \( \vec{\mu} \) that are possible candidates for the minimum have to satisfy the condition \( \mu_i \in \{\gamma, \delta, 0\} \). Let \( n \) be the number of entries where \( \mu_i = \gamma \) and \( m \) the number of entries where \( \mu_i = \delta \). The minimization problem has been reduced considerably: For fixed \( n, m, n + m \leq d \), we minimize the function

\[ n h(\gamma) + m h(\delta) , \] (14)

where \( h(x) = -x \log x \) under the constraints

\[ \{ n \gamma + m \delta = 1 , n \sqrt{\gamma} + m \sqrt{\delta} = \sqrt{2F} \} , \] (15)

The constraints give rise to a quadratic equation in \( \sqrt{\gamma} \) which provides two possible solutions for \( \gamma \) for every choice of \( n, m \):

\[ \gamma_{nm}^\pm (F) = \left( \sqrt{2F} n \pm \sqrt{mn(m + n - dF)} \right)/n(n + m) \] (16)

\[ \gamma_{nm}^\pm = \delta_{nm}^\pm \] respectively.

With the first constraint we get the corresponding \( \gamma_{nm}^\pm = (1 - n \gamma_{nm}^\pm)/m \). Since \( \gamma_{nm}^- = \delta_{nm}^+ \), the
function in Eq. (14) takes the same value for \( \gamma_{nm}^+ \) and \( \gamma_{nm}^- \). Therefore we can restrict ourselves to the solutions \( \gamma_{nm} := \gamma_{nm}^+ \). The pointwise minimum over all possible choices for \( n, m \) of

\[
R_{nm}(F) = H_2(n\gamma_{nm}) + n\gamma_{nm} \log \frac{n}{m} + \log m,
\]

defined on the domain \( \frac{n}{d} \leq F \leq \frac{m}{d} \), is the required function \( R(F) \). The restriction on the domain comes from requiring that \( \gamma_{nm} \) is a proper solution of Eq. (16) which implies that \( F \leq \frac{n+m}{d} \). On the other hand we demand that \( \delta_{nm} \geq 0 \) which implies that \( F \geq \frac{n}{d} \). In this regime one can verify that \( \gamma_{nm} \geq \delta_{nm} \).

When \( m = 0 \), \( \gamma \) and \( F \) are uniquely determined by the constraints, i.e. \( F = \frac{n}{d} \). Since \( R_{n0}(\frac{n}{d}) = R_{n'm'}(\frac{n}{d}) \) for all \( n' + m' = n \), we can neglect these cases.

When \( d = 3 \), what remains is a minimization over the three functions \( R_{12}(F) \), \( R_{21}(F) \) and \( R_{11}(F) \), which are plotted in Fig. 3. For \( d = 3 \) we get \( R(F) = R_{12}(F) \) [3]. Thus the optimal vector \( \bar{\mu} \) is always of the form

\[
\bar{\mu} = \{\gamma, \delta, \delta\},
\]

satisfying \( \gamma \geq \delta \).

The case \( d = 3 \) is the important one, since it turns out that we can relate all the higher dimensional minima to \( d = 3 \) and prove that

**Lemma 2** For \( d \geq 3 \) the function \( R(F) = R_{1d-1}(F) \).

**Proof** The case \( d = 3 \) is discussed above. Note that \( R_{1d-1}(1/d) = 0 \), which is clearly minimal, so we provide a proof for \( F > 1/d \). Let the minimum be attained in \( d > 3 \) dimensions by a vector \( \bar{\mu} = \{\mu_i\} \). Let us select some subset of the entries of \( \bar{\mu} \), the set \( \{\mu_i\}_{j=1}^{d'} \), where \( \sum_{j=1}^{d'} \mu_i = k \leq 1 \). Since \( \bar{\mu} \) is the minimum, it follows that the set \( \{\mu_i\}_{j=1}^{d'} \) is the minimum when we keep the other entries of the vector \( \bar{\mu} \) fixed. Let \( \mu_j' := \frac{\mu_j}{k} \). The vector \( \mu' \) is the solution for the minimization of

\[
\sum_{i=1}^{d'} h(\mu_i'k) = k \left[ \sum_{i=1}^{d'} h(\mu_i') \right] + h(k),
\]

under the constraints \( \sum_{j=1}^{d'} \mu_j' = 1 \) and \( \sum_{j=1}^{d'} \sqrt{\mu_j'} = C \) where

\[
C = \sqrt{\frac{dF}{k}} - \frac{1}{\sqrt{k}} \sum_{i:j,i \neq j} \sqrt{\mu_i}.
\]

This last equation can always be written as \( C = \sqrt{dF} \) for some \( F' \). Thus the restricted minimization problem is equivalent to a \( d' \)-dimensional version of the original problem, up to the scaling factor \( k \) and the additive term \( h(k) \). When \( F' \leq \frac{1}{d} \), we know that solution of this minimization problem is given by a Schmidt vector \( \bar{\mu}' \) which corresponds to an unentangled state, i.e. it is of the form \( \bar{\mu}' = \{1, 0, \ldots, 0\} \). Let us choose three arbitrary \( \mu_i \) out of the optimal vector \( \bar{\mu} \). When the resulting \( F' \leq \frac{1}{d} \), it follows that \( \bar{\mu}' = \{1, 0, 0\} \). When \( F' > \frac{1}{d} \), the three entries of \( \bar{\mu}' \) have to satisfy Eq. (18). So in fact, in both cases they satisfy Eq. (18). Suppose now that one entry of \( \bar{\mu} \) is equal to zero. Then it follows that \( \bar{\mu} \) cannot have two nonzero entries since this would violate condition (18), in other words it must be that \( \bar{\mu} = \{1, 0, \ldots, 0\} \). But this is a solution for \( F = 1/d \). Therefore we get \( n + m = d \) for \( F > 1/d \). Suppose that \( n \geq 2 \). We can choose the vector \( \{\gamma, \gamma, \delta\} \) satisfying \( \gamma \geq \delta \). Then condition (18) implies that \( \gamma = \delta \). This implies that all entries of \( \bar{\mu} \) are identical, or \( \bar{\mu} = \{1, 1, \ldots, 1\} \). This corresponds to a maximally entangled state, which is the unique solution for \( F = 1 \). Therefore \( n = 1 \) and \( m = d - 1 \). □

Lemma 1 and Lemma 2 together result in

**Theorem 1** The entanglement of formation \( E(\rho_F) \) for isotropic states in \( C^d \otimes C^d \ (d \geq 2) \) for \( F \in (1/d, 1) \) is given by

\[
E(\rho_F) = \text{co}(R_{1d-1}(1)),
\]

where

\[
R_{1d-1}(F) = H_2(\gamma(F)) + (1 - \gamma(F)) \log (d - 1),
\]

with

\[
\gamma(F) = \frac{1}{d} \left( \sqrt{F} + \sqrt{(d - 1)(1 - F)} \right)^2.
\]
For $d = 3$ the first and second derivative of the function $R_{1, d-1}(F)$ are plotted in Fig. 2. The figure shows that the function $R_{1, d-1}(F)$ is not convex near $F = 1$; its second derivative is not positive. In order to determine $\text{co}(R_{1, d-1}(F))$ for $d = 3$ we solve the following equations. Let $E_{\text{line}}(F) = a F + \log 3 - a$ be the line crossing through the point $(1, \log 3)$. We solve (1) $E_{\text{line}}(F) = R_{1, d-1}(F)$ and (2) $dE_{\text{line}} / df = a = dR_{1, d-1} / df$ for $a$ and $F$. Figure 2 indicates that $R_{1, d-1}(F)$ is monotonically increasing and that there is only one region where $R_{1, d-1}(F)$ is not convex, namely near $F = 1$. Therefore the solution to the equations will be unique: we find that $F = 8/9$ and $a = 3$. For higher dimensions, we conjecture, based on examining these two equations, that the entanglement of formation in $C^d \otimes C^d$ is given by

$$E(\rho_F) = \begin{cases} 0, & F \leq \frac{4}{3}; \\ \frac{1}{d} \log (d-1) - \frac{1}{d} \log (d-1) (F - 1) + \log d, & F \in \left[\frac{1}{d} \log (d-1), 1\right]. \end{cases}$$

(24)

The correctness of this solution can easily be verified for a given $d$ by plotting the function $R_{1, d-1}(F)$ and its second derivative and noting the convex hull of $R_{1, d-1}(F)$ is obtained by calculating where $R_{1, d-1}(F)$ meets the line going through the point $(F = 1, E = \log d)$ and the tangent of $R_{1, d-1}(F)$ equals the slope of this line.

It is surprising to find that $E(\rho_F)$ is nonanalytic in the region where $\rho_F$ is an entangled density matrix. Another feature of our solution is that for, say, $d = 3$ and $F > 8/9$ an optimal decomposition of $\rho_F$ is not one in which every pure state has an equal amount of entanglement. Indeed, the optimal decomposition that we find, is a mixture of the maximally entangled state and the ensemble of states $|\psi\rangle$ obtained by twirling, each of which has entanglement $E = -1/3 + \log 3$. Since every state in the optimal decomposition of $\rho_F$ has, under twirling, a value of entanglement on $R_{1, d-1}(F)$, every optimal decomposition of $\rho_F$ for $d = 3$ in the range $F > 8/9$ will be a mixture of the maximally entangled state and some less entangled states. This is in contrast with optimal decomposition for $E$ for two qubits. For $F > 8/9$ more than $d^2 = 9$ pure states must be used in the optimal decomposition of $\rho_F$. We make $\rho_F$ from a maximally entangled state and the state $\rho_F = s/9$ which has rank 9, and thus needs at least 9 states in its optimal decomposition. In total, this gives 10 states. For $F > 8/9$ there is no optimal decomposition with fewer states: one always has to mix in the maximally entangled state with some probability. The remaining state $\rho_F$ either has rank 9 (like $\rho_F = s/9$) or a lower rank. If it has a lower rank, it must be separable, which would imply that the optimal decomposition is made from mixing a separable state with a maximally entangled state which we know to be false. This is the first example of an entangled state for which it is proved that the number of pure states in the optimal decomposition exceeds the rank of the state (see Ref. [10] for separable states with this property).

Crucial in our method is the invariance of the isotropic states under a symmetry group of local operations. A result similar to Lemma 2 will hold for example for the class of Werner states [9] which are invariant under the transformation $U \otimes U$ for all $U \in U(d)$. Let $S^U \otimes U$ be defined as in Eq. (8), but with omission of the complex conjugation. The Werner states $\rho_p^W$ are characterized by a single parameter $p$. One can prove that $E(\rho_p^W) = \text{co}(R(p))$ where

$$R(p) = \min \{ E(|\psi\rangle\langle\psi|) \mid S^U \otimes U(|\psi\rangle\langle\psi|) = \rho_p^W \}.$$  

(25)

It may thus be possible to carry out a similar analysis as was done here for the Werner states. In a further generalization one could consider the entanglement of formation for $g \otimes g$ or $g \otimes g^*$ invariant states where $g \in G$ and $G$ is a subgroup of $U(d)$.
