Abstract To identify individual cells exposed to a X-ray microbeam in a cell population, we developed a biocompatible microchamber-array chip using UV lithography of photopolymer SU-8. The center-to-center distance between microchambers is 50 μm including a wall of 15 μm height. Using the microchamber-array chip, we performed tracking of individual exposed cells. Sample cells loaded in a microchamber array were selectively irradiated with the X-ray microbeam under microscopic observation. All the irradiated cells were indexed by the array arrangement of the microchambers. For about 24 h of post-irradiation incubation, the irradiated cells were identified successfully by time-lapse observation. In addition, the induction of radiation effects was observed in identified cells using immunofluorescence.

Introduction

In this decade of radiobiology research, microbeam systems of ionizing radiation have been developed to perform single cell irradiation in cell populations [1, 2]. Several researchers have revealed significant radiobiological effects with microbeams. One of them is the so-called “bystander effect” resulting from intercellular communication between cells exposed and unexposed to ionizing radiation [3]. Investigation of radiation responses in individual cells is necessary to understand the bystander effect. In normal culture system, however, the identification of individual cells is quite difficult in post-irradiation incubation because each cell moves randomly over the surface of the culture substrate [4].

Meanwhile, microfabricated devices for cell biology have increasingly been implemented in applied and basic biomedical research. This microtechnology provides researchers with new opportunities for the spatial and temporal control of cell growth environments [5–7]. For example, an on-chip observation system for isolated cells was proposed to study the fate of individual stem cells [8].

In this study, we developed a microchamber array to identify individual living cells for X-ray microbeam irradiation. A microchamber array was fabricated with UV lithography of photopolymer SU-8. Sample cells cultured in the microchamber array were irradiated selectively using an X-ray microbeam. In post-irradiation analysis, radiation effects of individual cells in a microchamber array were successfully observed with time-lapse microscopy observation and immunofluorescence technique.

Materials and methods

Fabrication of the microchamber-array chip

A microchamber array was fabricated with UV lithography of photopolymer SU-8. SU-8, which is solidified by the
exposure to UV light, is widely used as photofabrication material for its mechanical characteristics, optical transparency, manufacturability and biocompatibility [9]. A schematic drawing of the fabrication process of a microchamber array is shown in Fig. 1. A glass coverslip of 18 × 18 mm² was spin-coated with SU-8 3050 photoresist (Microchem) at 2000 rpm for 30 s. The SU-8 layer was soft-baked for 10 min at 95°C to evaporate the solvent and solidify the photoresist and exposed to 365 nm UV light (40 mW cm⁻², SX-UI 251HQ, USHIO) through a photomask for 30 min. After baking for 6 min at a 95°C, the SU-8 layer was developed in SU-8 developer (Microchem) for 5 min. The aluminum photomask was also fabricated with UV lithography. An aluminum evaporated (thickness: 500 Å) glass coverslip was spin-coated with THMR-ip 5700HP photoresist (TOKYO OHKA KOGYO CO., LTD.). The photoresist was baked at 90°C for 90 s and scanned with a focused UV laser (λ = 405 nm, CrystalLaser) to register a micro-pattern. After baking at 110°C for 90 s, the photoresist was developed for 60 s in NMD-3 2.38% (TOKYO OHKA KOGYO CO., LTD.). Lastly, the exposed aluminum layer was solved in 1% NaOH solution for 60 s and residual photoresist was removed in 60% dimethyl sulfoxide and 40% N-methyl-2-pyrolidone solution. We also used purchased photomasks with a 70 μm grid pattern (Edmund Optics) for the test fabrication.

Figure 2 shows photographs of a microchamber-array chip. The size of a microchamber is 50 × 50 μm², and the depth was measured to be 15 μm with laser microscope. To ensure biocompatibility, the microchamber-array chips were sterilized by autoclaving at 121°C for 15 min and then coated with 0.1% gelatin solution (ES-006-B, CHEMICON INTERNATIONAL) for 3 h.

Cell culture

Rat pheochromocytoma PC12 cells were used as test cells for the investigation of radiation effects induced by the X-ray microbeam. PC12 is widely used as in vitro neuron model cell [10]. Also, it is reported that the inflammatory cytokine interleukin-6 (IL-6) is produced under ionizing radiation in these cells [11]. IL-6 is known to induce various effects on neuronal cells [12–14], which might serve as signaling factors in ionizing radiation-induced intercellular communication. PC12 was obtained from Dr. Kushibiki (Osaka University, Osaka, Japan). Cells were cultured with Dulbecco’s modified Eagle’s medium (DMEM) containing 10% fetal bovine serum and 5% horse serum in a 5% CO₂ and 95% air humidified atmosphere at 37°C. The cells were subcultured once a week with a split ratio of 1:6.

Single cell irradiation

A schematic drawing of the X-ray microbeam irradiation with the microchamber-array chip is shown in Fig. 3. The tabletop X-ray microbeam system based on a commercial X-ray microscope was described previously [15]. Briefly, X-rays generated by a micro-focus X-ray tube (voltage: ~50 kV, current: ~1 mA) are collimated to 12 μm diameter [FWHM] with a glass capillary [16]. Maximum dose rate was estimated to be 0.3 Gy s⁻¹ with photon counting measurement and energy deposit simulation. Single cells can be irradiated manually by a control of the sample stage under microscopic observation. Regular objectives of 20× and 40× magnification are interchangeable to observe the sample cells. After irradiation, the cells on the microchamber-array chip were incubated according to the cell culture protocol.

Immunofluorescence stainings

In post-irradiation analysis, immunofluorescence stainings were performed to detect the production of IL-6 and γ-H2AX [17, 18]. As mentioned before, the autocrine induction of IL-6 in PC12 under ionizing radiation was reported. IL-6 is known to induce various effects on neuronal cells. We assumed that IL-6 from irradiated cell may interact with unirradiated cells in the bystander effect. It is known that γ-H2AX formation is rapidly induced at sites of

![Fig. 1 Schematic drawing of the fabrication process of a microchamber array](image-url)
DNA double-strand breaks (DSBs), and therefore it is widely used to visualize the DSBs [19]. After post-irradiation incubation, cells were fixed in 4% paraformaldehyde in phosphate-buffered saline (PBS) for 10 min on ice, washed in PBS and permeabilized in TNBS solution (PBS supplemented with 0.1% Triton X-100 and 5% bovine serum albumine (BSA)) for 30 min. Cells were washed and incubated with diluted 1:200 rat IL-6 primary antibody (SANTA CRUZ BIOTECH.) in PBS with 2% BSA overnight at 4°C or 1:500 γ-H2AX primary antibody (Molecular Probes) in PBS with 2% BSA for 90 min. After washing in TNBS, fluorescent second antibody Alexa Fluor® 488 (Molecular Probes), diluted to 1:250, was added for 60 min and the sample was then washed several times in TNBS. Hoechst 33342 was used for nuclear staining (0.5 μg mL⁻¹, 20 min). All samples were observed using a standard fluorescent microscope (IX71, Olympus) with mercury lamp excitation. To allow direct comparisons, all of the fluorescent images were obtained using the same microscopy parameters. The fluorescence intensity of γ-H2AX foci was measured with Adobe Photoshop 7.0 and ImageJ 1.38× softwares. For quantitative analysis, the mean grey values of foci per nucleus were obtained from γ-H2AX foci images extracted with a color filter. For each sample, cell measurement was performed until at least 20 cells were registered. Three independent experiments were performed for each data point.

Results and discussion

PC12 cells were seeded onto the microchamber-array chip in a 35 mm culture dish. Figure 4 shows the distribution of cell number in one microchamber at a cell seeding density of 5.0 × 10⁴, 7.5 × 10⁴ or 1.0 × 10⁵ cells mL⁻¹, respectively. The number of chambers containing a single cell was not proportional to the cell seeding density, because at

**Fig. 3** Schematic drawing of X-ray microbeam irradiation with a microchamber-array chip. X-ray microbeam is incident on the upper surface of a cell. In microbeam irradiation, a microchamber-array chip was picked up from a culture dish and coated with a kapton film of 7 μm thickness to prevent air contamination. The sample chip is set on a sterilized sample stage.

high density, the cells readily attached to each other before dwelling in the microchamber.

At 24 h after cell seeding, the viability of the PC12 cells in the microchambers was tested with the viability and pH indicator BCECF-AM reagent (Molecular Probes) [20]. BCECF-AM is a fluorescein derivative that is cleaved to a fluorescent product by non-specific esterase present in living cells. In Fig. 5, the strong fluorescence spots indicate that the respective cells in the microchambers are alive.

Cells were seeded at a density of $5.0 \times 10^4$ cells mL$^{-1}$ onto a microchamber-array chip 24 h before X-ray microbeam irradiation. During irradiation, all the irradiated cells were indexed via the array arrangement of the microchambers. During post-irradiation incubation, tracking of irradiated cells was performed with time-lapse microscopic observation. Figure 6 shows time-lapse photographs of individual PC12 cells in microchambers. After incubation, the induction of radiation effects was checked in irradiated cells with fluorescence analyses. At 24 h after irradiation, IL-6 production was clearly observed in cells exposed to 6 Gy of X-ray microbeam (Fig. 6).

Cell death induced by X-ray microbeam irradiation was estimated by propidium iodide test (10 $\mu$M for 10 min) and counting missing cells due to detaching from a substrate. Approximately 60% of the cells irradiated with 6 Gy did not survive at 24 h after irradiation. Next, we investigated the time-course of DNA damage in PC12 cells. Irradiated cells were observed in microchambers at 1, 3, 9 and 24 h after X-ray microbeam irradiation. Figure 7 shows the
time-course of fluorescent intensity of γ-H2AX foci. Most of the γ-H2AX signal was eliminated on surviving PC12 cell at 24 h after irradiation, reflecting DNA DSB repair [21].

In summary, we developed a biocompatible microchamber array with UV lithography of photopolymer SU-8. The microchamber array was found to be useful to analyze radiation effects induced by an X-ray microbeam in individual cells. The microchamber array may be applied in a similar manner to particle microbeam irradiation experiments. Microfabrication of SU-8 on a thin substrate to deliver particle beams from lower surface of a cell was described [22]. We believe that observation techniques based on microchamber arrays might become standard platforms to study single cell irradiation.

Acknowledgments The authors appreciate Dr. Kushibiki (Osaka University), Dr. Matsumoto (Tokyo Institute of Technology), Dr. Kodama and Dr. Shiraishi (University of Osaka Prefecture) for helpful advises and discussion of biological experiments.
