(Received July 28, 2015)

High-rate production of methane from acetate using a fixed-bed reactor filled with marine sediment containing halotolerant aceticlastic methanogens and 3 % NaCl was investigated. In continuous culture, the methane production rate increased with increasing dilution rate. The maximum methane production rate of 750 mM d−1 was observed at a dilution rate of 16.2 d−1, which is impossible without immobilization of the cells in the sediment. Using scanning electron microscopy, we observed Methanosarcina-like filamentous microorganisms and Methanosaeta-like coccoid microorganisms in granule-like structures. The results demonstrated that marine sediment is not only a promising microbial resource of halophilic aceticlastic methanogens, but also a supporting material to fix aceticlastic methanogens in a fixed-bed reactor.

Keywords
Methane, Acetate, Aceticlastic methanogen, Fixed-bed reactor, Saline condition

1. Introduction

Methane fermentation is employed worldwide for organic waste treatment and energy recovery from various kinds of organic matter including manure, food, and municipal wastes. However, methane fermentation using common anaerobic technologies in saline condition (>3 %) is often difficult because of inhibitory effect by salinity. Methane fermentation occurs in complex microbial ecosystems, in which organic matter is converted to methane in three steps: hydrolysis/acidogenesis, acetogenesis, and methanogenesis. In the first step, organic matter is converted to volatile fatty acids (VFAs) by various bacteria. Then, VFAs such as propionate and butyrate are converted to acetate and hydrogen by propionate- and butyrate-oxidizing bacteria, respectively. The final step of methane fermentation, formation of methane from CO2 with H2 is promoted by the activity of hydrogenotrophic methanogens, whereas acetate degradation can proceed through two different pathways: direct cleavage of acetate by aceticlastic methanogens or syntrophic acetate oxidation (SAO). The aceticlastic methanogens cleavage methyl group of acetate into methane, while the carboxyl group is converted into CO2. On the other hand, SAO is a two-step reaction in which acetate is primarily oxidized to H2 and CO2 by SAO bacteria, followed by the subsequent reduction of CO2 with H2 to methane by hydrogenotrophic methanogens (SAO-HM pathway). It has been reported that most of the methane (approximately 65-80 %) generated from fermentation is derived from direct cleavage of acetate by aceticlastic methanogens or syntrophic acetate oxidation (SAO). However, recent studies have reported a significant contribution by SAO-HM pathway to the production of methane under inhibitory conditions such as the level of ammonium-nitrogen, acetate concentration, or the synergistic stress of acids and ammonium, dilution rate, temperature and prevailing methanogenic population structure. Nevertheless, it is generally assumed that direct cleavage of acetate is important and predominant pathway though depending on the environmental conditions. Hence, aceticlastic methanogens play an important role in methane fermentation. Only two genera, Methanosarcina and Methanosaeta, are known to be aceticlastic methano-
bacteria such as short HRT and low pH, may be inhibitory to methane-forming bacteria\(^{17}\). On the other hand, in a two-stage system, different microbial phases are separated. In such systems, the hydrolytic and acidification phases may occur in the first reactor, while acetogenesis and methanogenesis occur in the second reactor. The concept of two-stage digestion is driven by separate optimization of each step, in which different types of microorganisms with different physiology participate. Therefore, two-stage system has several advantages over conventional one-phase processes, such as increased stability of the process by controlling the acidification-phase in order to prevent overloading and the build-up of toxic material, and higher organic loading rates and shorter HRT, resulting in potentially higher yields of biogas in smaller digesters than in one-stage reactors\(^{16,17}\).

Application of marine aceticlastic methanogens for conventional processes in a second reactor in two-stage digestion would enable treatment of organic wastes with high salinity\(^{60,18,19}\). We recently reported that the aceticlastic methanogen \textit{Methanosaeta} sp. strain H\(_A\), highly enriched from marine sediment collected from Hiroshima Bay, exhibited growth at 2.06 M (corresponding to 12 \%) NaCl\(^{20}\). Therefore, we investigated continuous methane production from acetate by enriched \textit{Methanosaeta} sp. strain H\(_A\) in a glass column reactor packed with a polypropylene/ceramic mixture as support material for fixation of \textit{Methanosaeta}\(^{20}\). In this set-up, methane production rate under 3 \% NaCl was 70 mM d\(^{-1}\). However, we had previously reported that microbial consortia in coastal mud sediment produced methane from acetate originating from organic matter in the sediment at the higher rate of 96 mM d\(^{-1}\) under 3 \% NaCl\(^{12}\). This suggested that inorganic, small silt in the sediment is a promising candidate for fixing aceticlastic methanogens, allowing higher methane production from acetate than artificial support carriers. However, since the acetate concentration was limited to the amount of organic matter in the marine sediment, the potential of the sediment as support material was not fully characterized.

Therefore, in this study, we attempted high-rate of methane from acetate with acclimated aceticlastic methanogens derived from marine sediment under 3 \% NaCl.

2. Materials and Methods

2.1. Source of Inoculum and Culture Media

Marine sediment was collected from the coastal seabed of Hiroshima Bay as reported previously\(^{21}\). The sediment samples were refrigerated at 4 °C until use. Artificial seawater containing 30 g NaCl, 3.0 g MgSO\(_4\cdot7H_2O\), and 0.053 g CaCl\(_2\cdot5H_2O\) per L of deionized water was used for acclimatization of the anaerobic marine sediment microbiota. The pH of the artificial seawater was adjusted to 8.0 with 1 M NaOH. Basal medium was employed for all experiments except for the acclimatization. The composition of the basal medium was as follows: 0.3 g KH\(_2PO_4\), 1.0 g NH\(_4\)Cl, 0.1 g MgCl\(_2\cdot6H_2O\), 0.08 g CaCl\(_2\cdot2H_2O\), 4 g KHCO\(_3\), 30 g NaCl, 5.0 g sodium acetate, 1.0 mg resazurin, 10 mL vitamin solution, and 10 mL trace element solution. The vitamin solution contained 2.0 mg biotin, 2.0 mg folic acid, 10.0 mg pyridoxine HCl, 5.0 mg thiamine HCl:2H\(_2\)O, 5.0 mg riboflavin, 5.0 mg nicotinic acid, 5.0 mg calcium-pantothenate, 5.0 mg p-aminobenzoic acid, 5.0 mg lipoic acid, and 0.1 mg vitamin B\(_3\). The trace element solution contained 12.8 g nitrilotriacetic acid, 1.35 g FeCl\(_3\cdot6H_2O\), 0.10 g MnCl\(_2\cdot4H_2O\), 0.024 g CuCl\(_2\cdot2H_2O\), 0.10 g CaCl\(_2\)-2H\(_2\)O, 0.10 g ZnCl\(_2\), 0.025 g CuCl\(_2\)-2H\(_2\)O, 0.01 g H\(_2\)BO\(_3\), 0.024 g Na\(_3\)MoO\(_4\)-2H\(_2\)O, 1.0 g NaCl, 0.12 g NiCl\(_2\)-6H\(_2\)O, and 0.026 g Na\(_2\)SeO\(_3\)-5H\(_2\)O.

2.2. Continuous Culture in a Fixed-bed Reactor

The marine sediment was acclimated to stimulate methane production. Hereto, batch culture was performed in 700-mL vials using artificial seawater at 37 °C for approximately six months. After acclimation, the sediment was transferred [30 \% (v/v) inoculum] into a column reactor with a gas-liquid-solid separator and with a volume of 640 mL (Fig. 1). Continuous culture was performed in basal medium with 3 \% NaCl, with an initial dilution rate of 2.0 d\(^{-1}\). The dilution rate was gradually increased during culture.

2.3. Batch Culture

After continuous culture of the marine sediment in the reactor, the sediment was harvested and inoculated [30 \% (v/v) inoculum] in 120-mL serum vials containing basal medium without acetate, and incubated at 37 °C. After the acetate was completely consumed, the sediment was used as inoculum.

To measure the specific growth rate of aceticlastic methanogens in the sludge, triplicate cultures [10 \% (v/v) inoculum] in 120-mL serum vials containing 50 mL of basal medium with 5 g L\(^{-1}\) of sodium acetate were employed, and the amount of methane produced in the log-arithmic growth phase (within 7 days) was measured. To test the effect of the acetate concentration on the
specific growth rate, the acetate concentration in the basal medium was varied from 0.5 to 200 mM and batch culture was performed as described above. Mixed liquor volatile suspended solid (MLVSS) was determined as described previously\(^2\). Specific growth rates (\(\mu\)) was calculated during the exponential phase, as described previously\(^2\),\(^3\).

2.4. Scanning Electron Microscopy (SEM)

For SEM, acclimated sludge was sampled from the reactor after completion of continuous culture. The solid fraction including cells was harvested by centrifugation at 10,000 \(\times\) g for 10 min, washed three times with 0.1 M phosphate buffer (pH 7.2), and fixed with 2.5 % glutaraldehyde in 0.05 M phosphate buffer (pH 7.2) for 2 h at 4 °C. The sample was then washed three times with 0.1 M phosphate buffer (pH 7.2), fixed with a 2 % solution of osmium tetroxide for 2 h at 4 °C, and dehydrated by successive transfer to 50, 70, 80, 90, 95, and 99.5 % solutions of ethanol and \(t\)-butyl alcohol. Subsequently, the sample was freeze-dried, mounted on stubs of a scanning electron microscope with patina paint, and sputter-coated with gold. The sections were examined and photographed using a JSM-5900 SEM (JEOL Ltd., Tokyo, Japan).

2.5. Chemical Analysis

The volume of CH\(_4\) generated during culture of methanogens was measured by displacing the gas with a saturated solution of NaCl. The concentration of methane was analyzed by gas chromatography (GC-8A; Shimadzu Corp., Kyoto, Japan) equipped with a thermal conductivity detector and a stainless steel column packed with activated carbon, at 70 °C. Argon was used as the carrier gas\(^4\). The concentration of acetate was quantified by high-performance liquid chromatography (LC-2000 Plus HPLC; JASCO Corp., Tokyo, Japan) equipped with a refractive index detector (RI-2031 Plus; JASCO Corp.), Shodex RSpak KC-811 column (Showa Denko K.K., Kanagawa, Japan), and a guard column (Shodex RSpak KC-G; Showa Denko K.K.) at 60 °C. Ultrapure water containing 0.1 % (v/v) phosphoric acid was used as the mobile phase at a flow rate of 0.7 mL/min\(^4\).

3. Results and Discussion

3.1. Effect of the Dilution Rate on the Methane Production Rate

Continuous culture in the fixed-bed reactor packed with acclimated marine sediment containing 3 % NaCl was performed with basal medium containing acetate as the sole carbon source at 37 °C and a low dilution rate (Fig. 2(A)). The initial dilution rate was 2.0 d\(^{-1}\). When the dilution rate was increased stepwise to 4.9 d\(^{-1}\), the acetate removal efficiency was maintained at ca. 97 % (Fig. 3(A)), and the methane production rate increased in proportion to the increasing dilution rate (Fig. 3(B)). The methane production rate reached 303 mM d\(^{-1}\) at 4.9 d\(^{-1}\) dilution rate. In aceticlastic cleavage of acetate by aceticlastic methanogens, the methyl group of acetate is converted into methane, while the carboxyl group is converted into CO\(_2\)\(^1\), i.e., 1 mol of acetate is converted into 1 mol of methane and 1 mol of CO\(_2\) theoretically. In this study, the ratio of methane production to acetate consumption was approximately equal (Fig. 3(C)) at this dilution rate, indicating that consumed acetate was completely converted to methane by the acclimated methanogenic sediment. To investigate the potential of the acclimated methanogenic sediment at high dilution rate, the dilution rate was gradually increased to 20 d\(^{-1}\) after treatment at 5 d\(^{-1}\) for 20 days (Fig. 2(B)). As the dilution rate increased, the acetate removal rate decreased (Fig. 3(A)). In contrast, the methane production rate increased step-wise until the dilution rate reached 16.2 d\(^{-1}\), but decreased subsequently (Fig. 3(B)). Similar to the low dilution rate conditions, the ratios of
methane production and acetate consumption were approximately equal at the high dilution rate (Fig. 3(C)).

In this study, a maximum methane production rate of 750 mM d⁻¹ with 77 % of acetate removal rate in 3 % NaCl was observed at a dilution rate of 16.2 d⁻¹. In our previous study, a maximum methane production rate of 96 mM d⁻¹ was achieved in a UASB reactor using acclimated methanogenic sludge from marine sediment under 3 % NaCl, with a dilution rate of 2.8 d⁻¹ and an acetate removal rate of 55 %²¹. Therefore, these results suggested that the performance of methane production by acclimated methanogenic sediment in 3 % NaCl has been dramatically improved in this study. Furthermore, methane production rate when using moving bed biofilm reactor (MBBR) and thermophilic down-flow anaerobic packed-bed reactor (TDPR) under condition without NaCl addition have been reported to be 183 mM d⁻¹ and 598 mM d⁻¹, respectively (Table 1). Hence, the maximum methane production rate of 750 mM d⁻¹ in this study was significantly higher than that of other reported conditions, demonstrating that the fixed bed reactor process with marine sediment as the support carrier was useful for efficient methane production from acetate.

3.2. Characteristics of Acclimated Aceticlastic Methanogens

In the batch culture of the acclimated marine sediment to investigate the specific growth rates (μCH₄) of acclimated aceticlastic methanogens under 3.0 % NaCl, a maximum specific growth rate of 0.152 h⁻¹ was obtained. The specific growth rate of the acclimated methanogen was higher than that of other known methanogens (Table 2).

To examine the acetate consumption under 3 % NaCl, the initial acetate concentration was varied from 0.5 to 200 mM. In the batch culture, the acetate was completely converted to methane in all conditions. Furthermore, when the initial acetate concentration was
150 mM, the specific acetate-consumption activity was 3.2 mmol g of MLVSS–1 h–1 (Fig. 4). It has been reported that *Methanosarcina barkeri* shows 0.7 mmol CH4 g of MLVSS–1 h–1 at 30 mM of initial acetate concentration22). Therefore, these results indicated that this acclimated methanogenic sediment possessed high acetate-consumption activity.

3.3. SEM of Acclimated Marine Sediment

SEM photographs of acclimated marine sediment derived from the fixed-bed reactor with acetate as a sole carbon source and with 3 % NaCl are shown in Fig. 5. Granule-like-structures were observed in the sediment (Fig. 5(A)). In the granule-like structures, *Methanosaeta*-like filamentous microorganisms (Fig. 5(B)) and *Methanosarcina*-like coccoid microorganisms (Fig. 5(C)) were observed.

Few species of halophilic *Methanosarcina* have been reported so far. The optimal NaCl range for growth of the halophilic aceticlastic methanogen *Methanosarcina acetivorans* was reported to be 0.1-0.6 M (corresponding to 0.6-3.5 %), and no growth occurred without NaCl24). *Methanosarcina mazei* strain Gö1 was able to grow at a concentration of 18,000 mg Na+ L–1 (4.6 % of NaCl equivalent)25).26). In contrast, only two species of halophilic and halotolerant *Methanosaeta* have been reported20),27). Aceticlastic halophilic *Methanosaeta pelagica* 03d30qT, isolated from tidal flat sediment, were able to grow at Na+ concentrations of 0.20 to 0.80 M (1.2 to 4.7 % of NaCl equivalent), with optimum growth at 0.28 M (1.6 % of NaCl equivalent)27).

We previously enriched and identified aceticlastic halotolerant *Methanosaeta* sp. strain Hs from the same marine sediment as that used in this study20). The morphology of this strain was quite similar to the *Methanosaeta*-like microorganisms observed by SEM in this study; however, the growth rate was lower than that of acclimated methanogens. Hence, we speculated that the collaboration between *Methanosarcina* and *Methanosaeta* resulted in the high-performance methane fermentation under saline condition.

4. Conclusion

High-rate production of methane from acetate under 3 % NaCl was successfully achieved using continuous culture in a fixed-bed reactor with marine sediment as the microbial resource of halophilic aceticlastic methanogens and as support material. In continuous culture, a maximum methane production rate of 750 mM d–1 with 77 % acetate removal rate was observed at a dilution rate of 16.2 d–1. Both *Methanosaeta*- and *Methanosarcina*-like microorganisms were observed in granule-like structures in the sediment. Our results indicated that acclimated methanogenic marine sediment might be applicable to high-rate methane production from acetate under saline condition.

海洋底泥を固定化担体および耐塩性酢酸発酵性メタン生成細胞として、3％の塩分濃度条件下での固定床型リアクターを用いた酢酸からのメタンの超高速生産を試みた。連続培養試験において、16.2 d-1の希釈率および3％の塩分濃度下で750 mM d-1の最大メタン生産効率が得られた。その際の酢酸除去率は77％であった。走査型電子顕微鏡による観察の結果、グラニュールの形成および Methanoseta 様の未熟種、 Methanosarcina 様の球菌が確認された。これらの結果から、海洋底泥は耐塩性メタン発酵の微生物源としてもだけでなく、酢酸からの超高速メタン生産を可能とする固定化担体としても優れていることが示唆された。
