Prevalence of small intestinal bacterial overgrowth syndrome among patients with inflammatory bowel disease and its impact on nutritional status and clinical manifestations

For citation: Gastroenterologìa. 2021;55(3):166-171. doi: 10.22141/2308-2097.55.3.2021.241586

Abstract. Background. In recent years, there has been high interest in the prevalence of small intestinal bacterial overgrowth (SIBO) syndrome in various populations. Chronic inflammatory bowel disease (IBD) is known to be a heterogeneous group of disorders, with a high degree of geographical variability in terms of symptoms, nature of progression, clinical manifestations, or combination with other types of pathologies. Since the involvement of the intestinal microbiome plays an important role in the etiopathogenesis of inflammatory bowel disease, the combination of SIBO and IBD is increasingly being considered and studied recently. Since the symptoms of both pathological conditions are significantly echoed, and therefore exacerbated by the combination, the manifestations of malnutrition become more pronounced, which negatively affects the nutritional status of patients with IBD. The purpose of the study is to determine the frequency of SIBO in patients with IBD depending on the nosological forms and to investigate its effect on clinical and laboratory indicators of nutritional status and clinical manifestations. Materials and methods. We examined 100 patients with IBD, aged 19 to 79 years, on average (42.54 ± 1.50) years, including 70 patients with ulcerative colitis (UC), and 30 — with Crohn’s disease (CD). All patients underwent general clinical examination, anthropometric measurements, general and biochemical blood tests (with the determination of total protein, albumin, prealbumin). To characterize the state of the small intestine microbiota (presence of SIBO), all patients underwent a hydrogen breath test with glucose loading using a Gastro® Gasotester gas analyzer from Bedford Scientific Ltd (UK).

Results. The analysis of SIBO frequency showed the changes in the state of the small intestinal microflora in 45 % of patients with IBD. The prevalence of SIBO was higher in the group of patients with CD — 53.3 % (16) than in the group with UC — 41.4 % (29). The presence of SIBO in the group of patients with UC had statistical significance and a direct correlation with the duration of the disease — (9.3 ± 6.2) versus (2.9 ± 3.1) years (p = 0.001, r = 0.55). There was a decrease in weight and body mass index (BMI) in patients with SIBO, especially in patients with Crohn’s disease, and accounted for (19.8 ± 3.5) kg/m². There was a significant difference between the levels of total protein in patients with SIBO and without it, both in the basic group and in the group of UC: (65.8 ± 8.4) g/l (p = 0.009, r = –0.232) and (66.5 ± 8.3) vs. (70.7 ± 7.4) g/l (p = 0.029), respectively, and albumin levels were reduced in both nosological groups. No relationship was found between the severity of abdominal pain and the presence of SIBO. When SIBO was detected, the manifestations of flatulence significantly prevailed in patients with UC — 75.8 % (n = 22), and diarrheal syndrome in patients with CD — 75 % (n = 12). Conclusions. The obtained results indicate a high prevalence of SIBO in patients with IBD. Patients with CD suffered from SIBO more often (53.3 %) than patients with UC (41.4 %) (with a predominance of patients with severe disease). A direct correlation of SIBO with the disease duration in patients with UC (r = 0.55, p < 0.05) was revealed, which is explained by the violation of physiological barriers that prevent the emergence of SIBO, due to more episodes of exacerbation, long-term use of drugs and concomitant pathology with time. The negative impact of SIBO on nutritional status manifested in weight loss, reduced BMI and other anthropometric (mid-upper arm circumference, mid-arm muscle circumference, triceps skinfold) and laboratory (total protein, albumin, prealbumin) parameters in these patients. The most common symptoms in patients with IBD with SIBO were abdominal pain, diarrhea, and flatulence that reflected the typical clinical picture of SIBO.

Introduction

Chronic inflammatory bowel disease (IBD), which is represented by ulcerative colitis (UC) and Crohn’s disease (CD), is gaining increasing attention due to the steady increase in morbidity and prevalence worldwide. Underinvestigated etiology and various hypotheses of the pathogenesis of these diseases lead to a deeper study of clinical features and mechanisms of systemic lesions in patients with UC and CD. This will allow the development of new, more accurate and personalized schemes for the diagnosis and treatment of these patients.

It is known that nutritional disorders are a common manifestation in patients with IBD, which significantly affects the course of the disease and worsens its prognosis. In addition to the common causes of nutrient loss in these patients (frequent bowel movements, chronic blood loss, enzymatic insufficiency, dietary restriction due to pain and intoxication), more and more attention has recently been paid to the changes in intestinal microbiota and their effects on inflammation, digestion and absorption [1, 2]. This is due to the fact that the most dominant etiological hypothesis indicates an immune response to the altered microbiota in a genetically predisposed host [3, 4].

One of the frequent manifestations of intestinal dysbiosis in patients with IBD is the small intestinal bacterial overgrowth (SIBO) syndrome. Some studies report a high pre-disposition to the development of SIBO in these patients, especially in patients with CD [1, 5–7].

The small intestine is a transition zone between the stomach, which contains a small number of microorganisms, and the large intestine with a high level of bacterial colonization. The small intestinal bacterial overgrowth syndrome develops with excessive colonization of bacteria in the small intestine due to opportunistic microflora of colon origin, including Streptococcus, Escherichia coli, Staphylococcus, Micrococcus, etc., and is accompanied by certain signs and symptoms depending on the type of bacteria in the intestine. Under physiological conditions, the proximal part of the small intestine is characterized by a bacterial population corresponding to $10^6–10^7$ colony-forming units (CFU) per milliliter of aspirate. SIBO is characterized by a population over $10^8$ CFU/ml aspirate [8].

The clinical picture of SIBO can be different: from asymptomatic to severe symptoms, such as constant abdominal pain, excessive flatulence, diarrhea. In severe cases, the symptoms manifested themselves as a consequence of malabsorption: vitamin $B_12$ deficiency or even iron deficiency anemia, deficiency of fat-soluble vitamins, hypalbuminemia, weight loss, signs of malnutrition, and even severe exhaustion [9]. Often these symptoms in patients with IBD are perceived as an outcome of the underlying disease and SIBO remains undetected. In turn, the accession of the SIBO to the next exacerbation of IBD significantly affects the severity of symptoms, severity, the possibility of complications, and the overall prognosis [7, 10].

The microflora of patients with SIBO is mainly characterized by the predominance of coliform bacteria and anaerobes, which cause fermentation of carbohydrates, compete with the absorption of vitamins and trace elements and provoke microscopic inflammation of the mucosa, which leads to the above symptoms [8, 11]. Most experts suggest that a culture of small bowel aspirate (with the number of bacteria in colonies $\geq 10^6$ CFU/ml) is the gold standard for the diagnosis of SIBO. However, this method has several disadvantages, the most important of which are the invasiveness of the procedure and the use of special equipment. The glucose hydrogen breath test (GBT) for the diagnosis of SIBO has gained increasing approval and is most commonly used in clinical practice (lactulose breath test and glucose breath test) [12]. The glucose hydrogen breath test is non-invasive and based on determining the concentration of hydrogen in the air exhaled after carbohydrate loading since there is a direct relationship between the degree of bacterial contamination of the small intestine and the concentration of hydrogen in exhaled air. However, it should be noted that the lactulose test is not suitable for the diagnosis of SIBO in patients with IBD, because lactulose is a synthetic disaccharide that does not break down and passes intact through the small intestine to the cecum, where it is metabolized by the colon bacteria to the short intestine, and gases, including hydrogen and/or methane, which are systematically absorbed and eventually exhaled. Due to accelerated intestinal transit in these patients, the test may give false-positive results (peak hydrogen concentration of 90 minutes or more) [12]. Therefore, GBT, due to its simplicity and high specificity, should be included in the list of mandatory studies in patients with IBD to detect SIBO in the early stages of diagnosis. This will allow timely correction of therapy and avoid complications, which in turn will improve the prognosis of the underlying disease.

So, the purpose of the study is to determine the frequency of SIBO in patients with IBD depending on the nosological forms and to investigate its effect on clinical and laboratory indicators of nutritional status and clinical manifestations.

Materials and methods

We examined 100 patients with IBD, aged from 19 to 79 years, on average (42.54 ± 1.50) years, including 70 patients with UC and 30 individuals with CD. In 51 cases with UC and in 11 with CD, there was a moderate severity of the disease; 19 patients with UC and 19 individuals with CD presented with severe disease. All patients underwent a general clinical examination to determine anthropometric parameters as well as a detailed collection of medical history and complaints.

Anthropometric parameters. Body mass index (BMI) was calculated by the formula:

$$BMI = \frac{m}{h^2}$$

where $m$ — body weight in kilograms; $h$ — height in meters. The triceps skinfold (TSF) was measured in millimeters with a caliper. The mid-upper arm circumference (MUAC) was measured in centimeters at the level of the middle third (midway between the acromion and the olecranon processes) of the non-working unstressed arm. The mid-arm muscle circumference (MAMC) was calculated by the formula:

$$MAMC = MUAC - 3.14 \cdot TSF.$$  

To characterize the condition of the small intestinal microbiota (presence of SIBO), all patients underwent a GBT using a Gas tro− Gastrolyzer gas analyzer from Bedfont Scientific Ltd (UK). Recommendations for preparing and conducting testing were as follows:

— avoidance of taking:

---

Vol. 55, No. 3, 2021  www.gastro.org.ua, http://gastro.zaslavsky.com.ua
– antibiotics for 4 weeks before testing,
– bismuth preparations and probiotics for 2–4 weeks before testing,
– prokinetics for 3 half-lives before testing;
– adherence to a diet that does not contain complex carbohydrates (pasta, bread, cereals, beans) in the evening before testing;
– night fasting before testing;
– avoidance of smoking before and during testing.

The study was conducted following the standards of GBT performance [13, 14]. The method is based on measuring the concentration of hydrogen in the air exhaled by the patient after ingestion of glucose solution (50 g per 250 ml of water), at regular intervals (0 min, 15 min, 30 min, 45 min, and 60 min). The GBT begins with the measurement of the basal level of H₂. To do this, the patient is asked to hold his breath for 15 seconds and then slowly exhale into the mouthpiece of the device. The hydrogen content is determined in parts per million (ppm), and diagnostically significant is the increase of its level by 12 ppm or more from the initial value.

The test can be started if the basal level of hydrogen in the exhaled air (on an empty stomach) does not exceed 5 ppm.

The results were processed using the Statistica 6.0 package. Since most of the data had a normal distribution, parametric statistics were used. The probability of the difference between the samples was evaluated by Student’s t-test, the differences were considered probable if p < 0.05. All quantitative indicators are given in the form of M ± m, where M is the arithmetic mean, m is the arithmetic mean error. Correlation analysis was performed using the Pearson correlation coefficient.

All measuring equipment used in the work was metrologically verified in the prescribed manner.

Results and discussion

The analysis of the frequency of SIBO showed that the changes in the state of the small intestinal microflora were observed in 45% of patients with IBD. The prevalence of SIBO was found to be higher in the group with CD — 53.3% of patients than in the group with UC — 41.4% of patients (Fig. 3).

It was also found that in the group of CD with detected SIBO, patients with severe disease prevailed, namely in 11 patients (68.7%) out of 16, while in the group of UC only 8 patients (27.5%) out of 29. This may be explained by the fact that most patients with CD had a predominant lesion of the terminal small intestine, and the accession of the SIBO had a negative impact on the severity of the disease. The presence of SIBO in the group of patients with UC had statistical significance and a direct correlation with the disease duration — (9.3 ± 6.2) versus (2.9 ± 3.1) years (p = 0.001, r = 0.55). No relation was found between the positive result of GBT and therapy for the underlying condition, which is confirmed by the literature resources [7].

We analyzed the relationship between the results of GBT and age, anthropometric and some laboratory parameters of patients (Table 1).

The groups of patients with positive and negative GBT did not differ in age or height. The average body weight of patients with a positive result of GBT was less than in those with a negative result: for UC — (64.0 ± 11.6) against (69.8 ± 17.8) kg, for CD — (58.3 ± 13.8) against (63.3 ± 12.5) kg, but the difference was not statistically significant. Body mass index was lower in patients with CD and positive SIBO — (19.8 ± 3.5) kg/m².
There was a significant difference between the levels of total protein in patients with SIBO and without it, both in the basic group and in the group of UC: (65.8 ± 8.4) vs. (70.2 ± 8.2) g/l (p = 0.009, r = −0.23) and (66.5 ± 8.3) vs. (70.7 ± 7.4) g/l (p = 0.03), respectively. Albumin levels were also reduced in both nosological groups with detected SIBO but were significant only in the UC group — (36.3 ± 9.2) g/l (p = 0.009, r = −0.35) (Table 2).

This indicates a violation of the processes of digestion and absorption in the small intestine. The correlation analysis in the UC group revealed a reversible relationship between the indicators of MUAC and MAMC and the presence of SIBO (r = −0.240, r = −0.235, respectively).

The data from a detailed survey of the patient’s data on the most common complaints and symptoms were analyzed. The results depending on the presence of SIBO and nosological group are shown in Fig. 4 and 5.

The most common symptom in the groups was abdominal pain. Almost all patients complained about it, regardless of the nosological form or the presence of SIBO. Dry skin was also a common symptom in patients with SIBO in both nosological groups (41.4 % (n = 12) in patients with UC and 56.3 % (n = 9) in patients with CD) and indicated an increase in the general manifestations of malnutrition. In SIBO, however, the indicators were not statistically significant.

Diarrhea is known to be a common clinical manifestation in patients with IBD. However, in some cases, the increase in the frequency of defecation in these patients is associated with the presence of SIBO. In our study, the diarrheal syndrome was observed in almost the same number of patients with UC regardless of the presence of SIBO. Manifestations of flatulence significantly prevailed in patients with UC with detected SIBO — 75.8 versus 26.8 % in patients without SIBO that reflects the typical clinical picture of SIBO.

In contrast, in the group of patients with CD, the diarrheal syndrome significantly prevailed in patients with positive SIBO: 75.0 % (n = 12) versus 28.5 % (n = 4). It can therefore be concluded that SIBO exacerbates the mani-

### Table 1 — Anthropometric, clinical, and laboratory indicators in the basic group of IBD, M ± m

| Indicator         | IBD (n = 100) | p     |
|-------------------|---------------|-------|
|                   | Positive GBT (n = 45) | Negative GBT (n = 55) |       |
| Age (years)       | 43.0 ± 14.8   | 41.9 ± 15.4   | 0.717 |

| Disease duration (years) | 6.1 ± 6.3 | 4.8 ± 4.9    | 0.237 |

### Table 2 — Anthropometric, clinical, and laboratory parameters depending on the nosology, M ± m

| Indicator         | UC (n = 70) | p     |
|-------------------|-------------|-------|
|                   | Positive GBT (n = 29) | Negative GBT (n = 41) |     |
| Age (years)       | 46.5 ± 14.1 | 43.8 ± 15.7 | 0.469 |
| Weight (kg)       | 64.0 ± 11.6 | 69.8 ± 17.8 | 0.134 |
| Height (m)        | 1.60 ± 0.08 | 1.70 ± 0.07 | 0.655 |
| BMI (kg/m²)       | 22.3 ± 3.3  | 24.0 ± 5.6  | 0.143 |
| MUAC (cm)         | 25.6 ± 2.7  | 27.3 ± 4.0  | 0.052 |
| TSF (cm)          | 0.94 ± 0.10 | 0.98 ± 0.20 | 0.408 |
| MAMC (cm)         | 22.6 ± 2.7  | 24.2 ± 3.6  | 0.049 |
| Total protein (g/l) | 66.5 ± 8.3 | 70.7 ± 7.4  | 0.029 |
| Albumin (g/l)     | 36.3 ± 9.2  | 42.0 ± 8.5  | 0.009 |
| Prealbumin (g/l)  | 19.8 ± 9.9  | 21.1 ± 12.7 | 0.707 |
| Disease duration (years) | 9.3 ± 6.2 | 2.9 ± 3.1   | 0.001 |
festations of this symptom in patients with CD in the active phase. However, it should be borne in mind that SIBO can mimic exacerbations of CD, including increased bowel movements and weight loss, so it should be detected in the early stages of diagnosis and treatment.

**Conclusions**

Thus, our results indicate a high prevalence of SIBO in patients with IBD — 45%. The prevalence of SIBO was higher in the group of patients with CD than in patients with UC — 53.3 and 41.4%, respectively. SIBO was more common in patients with severe CD, namely 68.7%, while in the group of UC only 27.5%.

There is a direct correlation between the duration of the disease and the presence of SIBO in patients with UC (r = 0.55, p < 0.05) that is explained by the violation of physiological barriers that prevent the emergence of SIBO, more episodes of exacerbation, prolonged use of drugs, and concomitant pathology in time.

The laboratory study found a significant decrease in total protein and albumin in patients with SIBO. They also showed a tendency to decrease body weight, BMI, and other anthropometric parameters (MUAC, MAMC, TSF) that indicates the negative impact of SIBO on the nutritional status of patients. The most common symptoms in patients with IBD and SIBO were abdominal pain, diarrhea, and flatulence that reflected the typical clinical picture of SIBO. But we should not forget that the clinical manifestations of SIBO and IBD often resonate and can be perceived as an exacerbation of the underlying disease. That is why it is necessary to timely diagnose SIBO in this group of patients, which will allow timely correction of disorders of the intestinal microbiota and avoid the strengthening of basic therapy.

Poшкодження синдрому надлишкового бактеріального росту серед пацієнтів із хронічними запальними захворюваннями кишечника, його вплив на показники нутритивного статусу та клінічні прояви

Резюме. Актуальність. Останніми роками спостерігається висока зацікавленість щодо поширеності синдрому надлишкового бактеріального росту (СНБР) у хворих на кишечну відповідь в різних популяціях. Відомо, що хронічні запальні захворювання кишечника (ХЗЗК) є гетерогенною групою розладів із високим ступенем географічної місця щодо симптомів, характеру прогресування, клінічних проявів або зв'язку з іншими типами патології. Зважаючи на те, що у хворих на ХЗЗК частота відгуків більш виражена, що може сказатися на нутритивному статусі пацієнта, наводяться дани про відсутність значних даних, що впливають на нутритивний статус пацієнтів із ХЗЗК.

Мета дослідження. Цілі: 1) визначити частоту і вплив СНБР в ХЗЗК на нутритивний статус; 2) проаналізувати асоціації СНБР з clinічніми проявами.

Матеріал та методи. Виконано дослідження на 100 пацієнтів з ХЗЗК: 43 жінки і 57 чоловіків з віком від 19 до 79 років. Діагноз ставлять на основі клінічних, антропометричних та лабораторних показників. Використовували методи безнітрового дихального тестирування Gastrolyzer (Bedfont Scientific Ltd, Великобританія) усім хворим з номерами збірки протягом 30 хвилин після відтанення від останнього харчування.

Висновки. За результатами дослідження встановлено, що відношення СНБР до клінічних проявів та антропометричних показників нутритивного статусу пацієнта з ХЗЗК варіюється від незначних до значних. У пацієнтів з СНБР було виявлено зниження ваги та індексу маси тіла, а також більшою кількістю епізодів загородження кишень. У пацієнтів з ХЗЗК, які відповідали умовному відсутніймі СНБР, була виявлена більш низька кількість епізодів загородження кишень.

Ключові слова: нутритивний статус, СНБР, пацієнти з ХЗЗК.
