The demand for vegetable oil, which is mainly used for dietary purposes and cooking, is steadily increasing worldwide. It is often desirable to reduce unsaturation levels of fatty acids in order to increase storage stability and reduce trans-fat generation during cooking. Functional disruption of FATTY ACID DESATURASE 2 (FAD2) prevents the conversion of monounsaturated oleic acid to polyunsaturated linoleic acid, thereby enhancing the production of the desirable oleic acid. However, FAD2 null alleles, due to growth defects under stress conditions, are impractical for agronomical purposes. Here, we aimed to attenuate FAD2 activity in planta while avoiding adverse growth effects by introducing amino-acid substitutions using CRISPR base editors. In Arabidopsis, we applied the adenine base editor (ABE) and cytosine base editor (CBE) to induce semi-random base substitutions within several selected FAD2 coding regions. Isolation of base-edited fad2 alleles with higher oleic acid revealed that the CBE application induced C-to-T and/or C-to-G base substitutions within the targeted sequences, resulting in an alteration of the FAD2 enzyme activities; for example, fad2-144 with multiple C-to-G base substitutions showed less growth defects but with a significant increase in oleic acids by 3-fold higher than wild type. Our “proof-of-concept” approach suggests that equivalent alleles may be generated in vegetable oil crops via precision genome editing for practical cultivation. Our targeted semi-random strategy may serve as a new complementary platform for planta engineering of useful agronomic traits.

Keywords: base editing, CRISPR, cytosine base editor, FAD2, oleic acid, vegetable oil

INTRODUCTION

Vegetable oils contain three types of saturated fatty acids, palmitic acid (16:0), stearic acid (18:0), and arachidic acid (20:0) and five types of unsaturated fatty acids, oleic acid (18:1Δ9), linoleic acid (18:2Δ9,12), linolenic acid (18:3Δ9,12,15), 11-eicosenoic acid (20:1Δ11), and erucic acid (22:1Δ13). They can be used in industrial applications or as edible oils depending on their fatty acid composition. It is highly desirable to reduce the polyunsaturated fatty acid content and to increase the oleic acid (18:1Δ9), which is less vulnerable to oxidation (Holman and Elmer, 1947; Liu and White, 1992). FATTY ACID DESATURASE 2 (FAD2), which synthesizes 18:2Δ9,12 fatty acid from
18:1 \( \Delta^9 \) fatty acid, was first identified as an endoplasmic reticulum (ER) membrane-bound protein (Okuley et al., 1994). The activity of FAD2 in plants is related to an increase in the content of dienoic fatty acids, hence increasing the resistance toward cold and salt stress, and is also known to affect development through salicylic acid (SA), abscisic acid, and jasmonic acid (JA) pathways (Martínez-Rivas et al., 2000; Kachroo et al., 2003; Regente et al., 2008).

Several attempts have been made to eliminate FAD2 function in plants in order to enhance desirable oleic acid production. In peanut and soybean, the FAD2 was knocked out using transcription activator-like effector nucleases (TALENs; Haun et al., 2014; Wen et al., 2018). Likewise, disruption of the FAD2 function in peanut, soybean, and camelina has been demonstrated via clustered regularly interspaced short palindromic repeats (CRISPR)/CRISPR-associated protein 9 (Cas9; Jiang et al., 2017; Do et al., 2019; Yuan et al., 2019). However, FAD2 null alleles are agronomically impractical because the loss of FAD2 function has adverse growth effects, resulting in a trade-off between reduction in yields and/or susceptibility to pathogens and increased oleic acid contents (Taylor et al., 2002; Anai et al., 2008; Pham et al., 2010). Of note, fad2 null mutations in Arabidopsis have been reported to cause dwarf phenotypes at a lower ambient temperature (Miquel et al., 1993) whereas an EMS allele fad2-1 appears to be more practical in terms of its growth phenotype (Lemieux et al., 1990). Targeting Induced Local Lesions in Genomes (TILLING) has been proposed as a useful approach for isolating point-mutant alleles for those genes, including FAD2, that lead to desirable agronomic traits and development as well (Lakhssassi et al., 2017).

Recently, derivatives of CRISPR/Cas9 systems have been developed to broaden the spectrum of CRISPR applications. One class of such derivatives is base editors (BEs), Nickase Cas9 (nCas9) fused to cytosine deaminase and to a laboratory-evolved adenine deaminase, referred to as a cytosine base editor (CBE; conversion of C to T) and an adenine base editor (ABE; conversion of A to G). These have been used to target deaminase domains to edit specific loci, without the need to generate double-strand breaks (DSBs), converting their respective nucleotides into other DNA bases (Komor et al., 2016; Nishida et al., 2016; Gaudelli et al., 2017). BEs can induce base substitutions leading to amino-acid change or splicing modifications. Two CBE systems, base editor 3 (BE3), and activation-induced cytidine deaminase (AID) adapt rAPOBEC1 from rat and PmCDA1 from sea lamprey as a cytidine deaminase domain, respectively (Komor et al., 2016; Nishida et al., 2016). CBEs often generate C-to-T substitutions as well via the BER (base excision repair) pathway, which served as a basis for the recent development of C-to-G base editors (Molla et al., 2020; Kurt et al., 2021; Zhao et al., 2021). Base editing has been applied to plants: the acetyl CoA carboxylase (ACCase) gene was modified in A. thaliana and Oryza sativa using enhanced ABE (Liu et al., 2020); Soybean flowering has been manipulated via amino-acid change within FLOWERING LOCUS T (FT), resulting from cytosine base editing (Cai et al., 2020); Watermelon and Brassica napus have been engineered to harbor herbicide resistance from the cytosine base editing in the ACETOLACTATE SYNTHASE (ALS; Tian et al., 2018; Wu et al., 2020).

In this study, we sought to generate FAD2 missense alleles by implementing ABE or CBE within several target regions of the FAD2 coding sequences in Arabidopsis. We selected those BE target sites for guide RNA (gRNA) design, based on the prediction of FAD2 protein structure, in order to generate genomic variations with base substitutions that are predicted to confer structural instability (Chavez Zobel et al., 2005; Li et al., 2020). For Agrobacterium-mediated plant transformation, we adapted the ABE binary vector, which has been reported in a previous study (Kang et al., 2018), and, for a CBE binary vector, we constructed a new pYY-RpAID vector based on plant-codon-optimized PmCDA fused to nCas9 under the control of RPS5A promoter. To isolate desirable FAD2 alleles with increased oleic acid, we carefully investigated 26 T1 transformants by measuring the oleic acid contents through massive gas chromatography (GC) analyses on their corresponding T2 seeds. As a result, we obtained novel FAD2 alleles showing significantly reduced desaturase activity, which led to enhanced oleic acid content. Genomic analyses confirmed that CBE implementation generated the desired novel missense alleles with multiple amino acid changes often resulting from the C-to-G rather than C-to-T substitutions. Our results also imply that our semi-random BE application to modify genes controlling important agronomic traits is a viable approach to produce novel designer alleles with new SNPs.

**MATERIALS AND METHODS**

**Plant Materials and Growth Conditions**

All experiments were conducted using Arabidopsis thaliana Columbia-0 (Col-0) and fad2-1 (Miquel and Browse, 1992) as an experimental control. Arabidopsis seeds were sterilized with 70% EtOH and 0.5% NaOCl and then were washed 7–8 times with distilled water before sowing. The seeds were subject to stratification at 4°C for 3 days. They were then grown in 1/2 MS media containing 1% sucrose in a culture chamber at 23°C with a 16-h-light/8-h-dark cycle. About 14-day-grown seedlings in MS media were transferred to soil for further growth.

**Plasmid Construction**

For basal CBE binary vector pYY-RpAID, plant (A. thaliana) codon-optimized coding sequences of PmCDA1 were synthesized by Integrated DNA Technology (Iowa, United States). First, pKI1.1R (Addgene #85808) (Shimada et al., 2010) was used to generate a pYY-RpEmpty vector, in which the original Cas9 sequences were removed, and two enzyme sites XmaI and XhoI were inserted instead. Nickase Cas9 (D10A) and the codon-optimized AID were PCR amplified to generate pYY-RpAID binary vectors by the infusion cloning method (Takara, Japan) onto an XmaI/XhoI-treated pYY-RpEmpty vector. The pYY-RpAID vector contains the following elements instead of the original Cas9 expression cassette from pK11.1R: RPS5A promoter-SV40 NLS-nCas9(D10A)-SV40 NLS-67aa linker-3X FLAG-PmCDA-SV40 NLS-UGI heat shock protein...
stratified for 3 days at 4°C. The germination tests were conducted on the seeds that had been germinated and grown in 1/2 MS media containing 1% sucrose and 50 ng·μl−1 hygromycin. Only surviving plants in the media were selected and transferred to soil for further analyses. Leaf genomic DNA was extracted (Edwards et al., 1991) for Sanger sequencing and was analyzed whether base editing had occurred within the FAD2 gene.

**Sanger Sequencing**

The PCR was performed on extracted genomic DNA as a template using Ex Taq (Takara) to generate FAD2 amplicons for subsequent sequencing analyses. A forward primer 5′-GCAATTTTCAACGCTTCA and a reverse primer 5′-TCATAACTTATTGTTGACGTA were used for 30-cycle PCR as following conditions: pre-denaturation (95°C for 5 min); denaturation (95°C for 30 s); annealing (52°C for 30 s); extension (72°C for 1 min); and post-extension (72°C for 10 min). A purification kit (Cosmo Genetech) was used to purify the PCR products. The quality and the quantity of the products had been determined using Nanodrop (Denovix) before the samples were deposited to a sequencing company (Bioneer).

**Fatty Acid Analysis**

The 100 seeds were used for the gas chromatography (GC) analysis. About 500 μl of 5% sulfuric acid solution was dissolved in methanol, and toluene was added to each sample. To quantify the fatty acid contents, 15.0 fatty acid was dissolved in sulfuric acid. Each sample immersed with the solution was subject to the reaction in a water bath at 85°C for 2 h. Each sample was then added by 1 ml of 0.9% NaCl. After that, 1 ml of hexane was added to the solution three times and then was centrifuged at 330 × g for 2 min. The supernatant was aspirated, transferred to a 6-ml tube, purified fatty acid methyl ester (FAME) using a nitrogen concentrator (Eylaa). The extracted FAME was dissolved in 200-μl hexane and then inserted into a GC vial. A DB-23 column (30 m × 0.25 mm, 0.25-μm film, Agilent) was used, and the extracted FAME was analyzed by GC-2030 (Shimadzu). The GC oven temperature was raised from 190 to 230°C at 3°C min−1.

**Germination Rate**

The germination tests were conducted on the seeds that had been stratified for 3 days at 4°C. The germination events were scored when the roots started to appear in 1/2 MS media, 1/2 MS with 150-mM NaCl, and 1/2 MS with 300-mM Mannitol. All 1/2 MS

culture on selective media, 26 T1 plants were collected for analysis of BE transgenes and transferred to soil for later GC analyses of T2 seeds. Individual pools of T2 seeds harvested from each T1 plant were subjected to parallel GC analyses to quantify their lipid compositions. Four independent T1 plants (named as g5CBE1-4) from the CBE constructs with g5CBE guide RNA showed increased oleic acid content in their T2 seeds (Supplementary Table 1). T2 seeds from g5CBE1, g5CBE2, g5CBE3, and g5CBE4 exhibited increased oleic acid contents up to 36.5, 36.2, 48.9, and 21.6%, respectively, while wild-type Col-0 and other transgenic lines (g1, g4CBEs and g2, g3, g4, g5, g6ABEs) oleic acid contents were no more than 20% (Supplementary Table 1; values with asterisks). Furthermore, g5CBE plants displayed decreased polyunsaturated fatty acid levels and increased eicosenoic acid (20:1Δ11) (Supplementary Table 1), implying that the desaturase activities of FAD2 protein had been compromised in those transgenic plants. We progressed to the next segregating T2 generation with g5CBE1 and g5CBE3, which had the highest amounts of oleic acid accumulation at their T2 seeds, in order to test whether bona fide cytosine base editing, which might be responsible for those increases, had occurred within the targeted FAD2 region in those transgenic plants. Notably, other gRNAs transformants did not show any significant changes in fatty acids in the T1 generation, which may be due to low levels of either base editing or oleic acid changes. We decided to focus on g5CBE lines for the following experiments.

Analyses of the Base-Editing Patterns and Lipid Contents From the fad2 Lineages

Seven (g5CBE11-17) and five T2 progenies (g5CBE31-35) from the g5CBE1 and the g5CBE3 T1 lineages, respectively, were analyzed for FAD2 genotypes (Figure 2A and Supplementary Figure 2). Genomic DNA extracted from leaves of the T2 plants was subjected to Sanger sequencing covering the CBE target region of the FAD2 gene (Figure 2A and Supplementary Figure 2). Interestingly, segregating C-to-G substitutions were observed at positions C2 and C12 in g5CBE11-16. Given that the protospacer adjacent motif (PAM) NGG sequences are regarded as the positions 21–23, these C-to-G substitutions are...
expected to result in the amino acid changes A295G and D298E, respectively (Figure 2A and Supplementary Figure 2). Among T2 plants, g5CBE12 and g5CBE14 appeared to have discrete C-to-G substitution chromatogram signals at the corresponding positions, indicating exclusive (A295G; D298E)-type amino acid changes had occurred (Figure 2A and Supplementary Figure 2). g5CBE11, g5CBE13, g5CBE15, and g5CBE16 showed mixed signals of C-to-G and C-to-T substitutions at the C2 position, and mixed signals of C and C-to-G at the C12 position (Figure 2A and Supplementary Figure 2). These results indicate that the edited bi-alleles at the C2 position and heterozygous C-to-G alleles at the C12 position had been transmitted to T2 plants. Of note, g5CBE17 showed all wild-type signals without any evidence of base editing events (Figure 2A and Supplementary Figure 2). Among g5CBE3 lineage, g5CBE31 plants also showed the A295G pattern from C-to-G conversion at the C2 position, accompanying with C-to-T conversion at C6 that would, anyway, result in synonymous mutation (Figure 2A and Supplementary Figure 2). In the g5CBE32, exclusive C-to-T substitutions occurred at the C2 position, resulting in A295V, and C-to-T and C-to-G at the C5 and C6 positions, respectively, resulting in T296M (Figure 2A and Supplementary Figure 2). In the g5CBE33 plant, heterozygous or mosaic C-to-T substitution at C2 was observed (Figure 2A and Supplementary Figure 2). The sequencing results for the g5CBE34 and g5CBE35 plants showed a mixed pool of sequencing traces, suggesting that larger genomic changes, such as indels, rather than point mutations might have occurred (Figure 2A and Supplementary Figure 2).

Gas chromatography analyses were then carried out on the corresponding T3 seeds from each T2 plant to investigate how the lipid composition had changed according to allelic differences with amino-acid changes. The oleic acid contents increased the most to 64.9, 63.9, and 69.2% in T3 progeny, and C-to-T and C-to-G at the C5 and C6 positions, respectively, resulting in T296M (Figure 2A and Supplementary Figure 2). In the g5CBE33 plant, heterozygous or mosaic C-to-T substitution at C2 was observed (Figure 2A and Supplementary Figure 2). The sequencing results for the g5CBE34 and g5CBE35 plants showed a mixed pool of sequencing traces, suggesting that larger genomic changes, such as indels, rather than point mutations might have occurred (Figure 2A and Supplementary Figure 2).

Gas chromatography analyses were then carried out on the corresponding T3 seeds from each T2 plant to investigate how the lipid composition had changed according to allelic differences with amino-acid changes. The oleic acid contents increased the most to 64.9, 63.9, and 69.2% in T3 progeny, and C-to-T and C-to-G at the C5 and C6 positions, respectively, resulting in T296M (Figure 2A and Supplementary Figure 2). In the g5CBE33 plant, heterozygous or mosaic C-to-T substitution at C2 was observed (Figure 2A and Supplementary Figure 2). The sequencing results for the g5CBE34 and g5CBE35 plants showed a mixed pool of sequencing traces, suggesting that larger genomic changes, such as indels, rather than point mutations might have occurred (Figure 2A and Supplementary Figure 2).

Gas chromatography analyses were then carried out on the corresponding T3 seeds from each T2 plant to investigate how the lipid composition had changed according to allelic differences with amino-acid changes. The oleic acid contents increased the most to 64.9, 63.9, and 69.2% in T3 progeny, and C-to-T and C-to-G at the C5 and C6 positions, respectively, resulting in T296M (Figure 2A and Supplementary Figure 2). In the g5CBE33 plant, heterozygous or mosaic C-to-T substitution at C2 was observed (Figure 2A and Supplementary Figure 2). The sequencing results for the g5CBE34 and g5CBE35 plants showed a mixed pool of sequencing traces, suggesting that larger genomic changes, such as indels, rather than point mutations might have occurred (Figure 2A and Supplementary Figure 2).

Isolation of the Base-Edited fad2 Alleles
We proceeded with g5CBE11, g5CBE14, g5CBE31, g5CBE32, g5CBE33, and g5CBE34 to the next T3 generation in order to isolate homozygous alleles and to verify whether the changes in fatty acid composition depend on possible T3 segregations (Figures 2A,B; the line numbers with asterisks). g5CBE11 was selected for a representative among the T3 group containing biallelic A295G/A295V along with heterozygous D298E mutations. g5CBE14 and g5CBE32 were for A295G; D298E and A295V; and T296M alleles, respectively, g5CBE31 had the A295G mutation and a synonymous C-to-T mutation. g5CBE33 was chosen for the heterozygous A295V allele. g5CBE34 was also included in this progression group in anticipation of the isolation of an indel allele in their T3 generation. Sanger sequencing analyses were performed in the T3 progenies of each allelic group. As a result, we successfully isolated all possible base-edited T3 homozygous alleles for each genotype represented by g5CBE114 (A295G; D298E), g5CBE144 (A295G; D298E), g5CBE316 (A295G), g5CBE321 (A295V; T296M), and g5CBE337 (A295V), hereafter referred to as fad2-114, fad2-144, fad2-316, fad2-321, and fad2-337, respectively (Figures 3A,B and Supplementary Figure 3). For the T3 progenies of g5CBE34, we isolated a 4-bp insertion mutation allele, named fad2-349 (frameshift mutation), presumably resulting in FAD2 knockout via a premature stop codon (Figures 3A,B and Supplementary Figure 3). Interestingly, segregating T3 progenies of g5CBE34 also present base-edited alleles (A295G), indicating that our CBE application had generated both base substitution and insertion mutations in a T2 g5CBE34 plant (Figure 3A and Supplementary Figure 3). The presence of a transgene was analyzed by PCR amplification of the nCas9 part for the T2 and T3 generations of g5CBE1 and g5CBE3 lines. The results indicate that the transgene had been segregated out from T3 in the g5CBE11 line and T2 in the g5CBE3 line (Supplementary Figure 4). Therefore, de novo additional base editing in the T3 generation was unlikely to have occurred.

Gas chromatography analyses carried out on all T3 genotypes revealed that all defined homozygous base-edited alleles showed significant increases in their oleic acid contents at their T4 seeds compared to wild-type Col-0 (Figures 3A,C and Supplementary Table 2). fad2-321 (A295V; T296M) showed the highest increase, in oleic acid content, up to 64.7 ± 5.7%, among the base-edited fad2 alleles (Figures 3A,C and Supplementary Table 2), which is consistent with observations in its parental T2 generation (Figure 2B). This increase is even higher than that of the previously reported fad2-1 (A104T) (Lemieux et al., 1990) (55.9 ± 1.9% in our analyses, Figure 3C and Supplementary Table 2), fad2-114 and fad2-144 (A295G; D298E) showed enhanced oleic acid production, up to 57.9 ± 5.4% and 56.5 ± 2.3%, respectively (Figures 3A,C and Supplementary Table 2), more than their segregating siblings (38 ± 2%; Figure 3A and Supplementary Table 2). The increases are likely due to the homozygous changes in two amino acids at the same time, which had been segregating and thus having shown moderate increases in the previous generation g5CBE11 as well (Figure 2B). Particularly, the linoleic acid (18:2) and the linolenic acid (18:3) contents were dramatically decreased to below 2.4% and to below 2%, respectively, in both fad2-321 and fad2-114, while those contents were 2.4 ± 0.2 and 6.2 ± 0.5% in fad2-1 (Figure 3C and Supplementary Table 2), supporting the notion...
that the increases are due to “attenuated” desaturase activities of FAD2 in those alleles. Notably, the oleic acid content of the attenuated allele, such as fad2-321, was comparable to that of a fad2-349 knockout allele in which the contents were measured as 59.5 ± 10.4% (Figures 3A,C and Supplementary Table 2).

Characterization of the Growth Responses of fad2 Alleles

We hypothesized that certain “attenuated” fad2 alleles in our study might not have as severe growth defects as the fad2 knockout allele, and possibly even less severe than the previously reported fad2-1 allele while maintaining increased oleic acid levels. In this regard, we decided to characterize our newly generated fad2 alleles for phenotypical differences in terms of their growth responses. We analyzed two early growth responses, i.e., germination and root growth rate, for each allele under normal and stress conditions. We used experimental stress conditions of 150-mM NaCl and 300-mM Mannitol, and 75-mM NaCl and 200-mM Mannitol on top of 1/2 MS media for the germination and root growth test, respectively, with the intention of mimicking salt or water-deficit stress as has been

FIGURE 2 | Characterization of the FAD2-targeting CBE-transgenic lines. (A) Chromatogram results from Sanger sequencing for FAD2 genotyping within editing windows in the T2 plants. The editing window is specified in the upper Col-0 panel. Red letters indicate altered DNA and amino-acid sequences. (B) Analysis of fatty acid compositions of transgenic lineages. Red-colored numbers denote the three most increased oleic acid contents observed among T2 plants analyzed. Asterisks (*) indicate the representative T2 transgenic lines that were progressed to the next T3 generation for further characterization.
described in previous studies (Zhang et al., 2012; Yu et al., 2017). For each of the alleles, germination tests were performed by scoring seed germination events at 12-h intervals during the initial 4 days after planting to assess whether increases in oleic acid content influence germination (Figures 4A–C). Under normal conditions, the germination frequencies of all tested alleles reached similar levels after 4 days, showing >95% germination success. Of note, fad2-349, fad2-321, and fad2-144 alleles did show slightly reduced germination rates (~72 h; Figure 4A), which coincide with relatively higher oleic acid contents observed in those alleles compared with others (Figure 3C). Upon both experimental stress conditions, fad2-349 and fad2-321 germination rates deteriorated sharply along with fad2-1, which showed significantly lower germination rates at all time points tested (Figures 4B,C). However, fad2-144, fad2-316, and fad2-337 maintained germination rates comparable to that of WT (Figures 4B,C). These results suggest that those fad2 alleles with increased oleic acid content also have enhanced resistance to stress susceptibility during germination in contrast to the case for fad2-1, fad2-349, and fad2-321 (Figures 4B,C). Notably, fad2-144, which showed one of the highest levels of oleic acid content and contains two concurrent amino acid
changes (A295G; D298E, Figure 3), was fairly resistant to the stress conditions tested for germination relative to \textit{fad2-1} (Figures 4B,C).

Next, we assessed root growth under normal or stress conditions by measuring root lengths of 4-day-old seedlings from each of the \textit{fad2} alleles (Figures 4D–F). Under normal growth conditions, all \textit{fad2} alleles tested showed a range of the root length reduction compared to wild-type Col-0 (Figures 4D,E). For example, \textit{fad2-144} and \textit{fad2-321} showed considerable reduction similar to the reduction observed in \textit{fad2-1} and knockout \textit{fad2-349} (Figures 4D,E), suggesting that the corresponding allelic changes impede normal root development. On the other hand, \textit{fad2-316} and \textit{fad2-337} appeared to have insignificant levels of root reduction (Figures 4D,E), indicating that their allelic variation does not alter normal growth processes. Stress treatments caused a range of reduction rates of root lengths on the seedlings from each allele tested (Figures 4D,E). Under the salt-stress condition, the knockout allele \textit{fad2-349} showed a reduction of root length to 55.8% of its length under the normal unstressed condition (Figure 4F), which is consistent with the reported growth defects in \textit{fad2} knockout mutants under salt stress. On the other hand, Col-0 and \textit{fad2-1} showed 66% and 63.6% of their normal growth lengths, respectively (Figure 4F). Notably, \textit{fad2-316} (A295G) and \textit{fad2-337} (A295V), which display an intermediate increase of oleic acids from single amino-acid substitutions (Figure 3C), showed less reduction in root length to 82.9% and 79.7%, respectively (Figure 4F). The result suggests that their growth might be even less affected by the salt stress condition than WT, \textit{fad2-144} (A295G; D298E) and \textit{fad2-321} (A295V; T296M), which were regarded as higher oleic acid-producing alleles with two concurrent amino-acid substitutions (Figure 3C), displayed 67.8 and 69.2% of relative root length under salt stress, similar to the reduction level observed in Col-0 (Figure 4F).

The growth defects seemed more obvious in the water-deficit stress condition with 200-mM Mannitol, as the root lengths on the seedlings from each allele tested (Figures 4D–F) were regarded as higher oleic-acid-producing alleles with two concurrent amino-acid substitutions (Figure 3C), displayed 67.8 and 69.2% of relative root length under salt stress, similar to the reduction level observed in Col-0 (Figure 4F).

Seed weight and fatty acid content of \textit{fad2} alleles were measured (Supplementary Figure 5). Compared to wild-type Col-0, the weight of \textit{fad2-1} was decreased, while the new \textit{fad2} alleles showed an increase. The fatty acid content of the seeds showed some differences between the new \textit{fad2} alleles. The fatty acid content per seed of \textit{fad2-1} was not significantly different from that of wild type. The allele produced in this experiment had an increase in seed weight compared to the wild type, and there was no difference or a significant increase in the fatty acid content per seed. These results suggest that mutations in the \textit{FAD2} gene can affect seed weight and fatty acid content. The correlation between \textit{FAD2} gene mutation and fatty acid content needs further study.

**DISCUSSION**

In our study, five different \textit{fad2} alleles were isolated for increased oleic acid via semi-random targeting of BEs to six different genomic regions of the \textit{FAD2} locus. All those higher oleic-acid alleles, interestingly, turned out to arise within the g5 gRNA targeting region, which represents the cytosolic stretch of ER-membrane-bound \textit{FAD2} protein. In principle, our laboratory-scale “pre-screen” may expedite the next process of recapitulating equivalent alleles in oil crops because one might focus on the corresponding g5 region to create such high oleic-acid variants via precision CBE targeting. Of note, the amino-acid residues harboring the allelic changes for increased oleic-acid content we have observed in our study are highly conserved in \textit{FAD2} loci across major oil crops, implying direct value in applications (Figure 5). The A295V change observed in \textit{fad2-321} and \textit{fad2-337} has been reported to be one of the four combinatorial mutations conferring the competence in hydroxyl fatty acid production by manipulating the \textit{FAD2} function into FAH12-like property (Broun et al., 1998), supporting the notion that the corresponding residue may be pivotal to \textit{FAD2} activity. We reasonably anticipate that recapitulating suitable alleles such as a \textit{fad2-144} equivalent in oil crops might be able to provide a clue to “agronomically applicable” genetic variants to mitigate adverse effects on plant growth and stress sensitivity that occurs in \textit{FAD2} knockouts under certain growth conditions. Even intensive base editing within corresponding g5 regions in oil crops again with ABE and CBE might provide desired results with much less effort than traditional approaches.

We proposed and demonstrated that our targeted “semi-random mutagenesis” approach adapting CRISPR/BEs as a mutagenic source might be an effective alternative to generate novel \textit{FAD2} alleles with desirable traits. All the reported \textit{FAD2} mutations thus far were generated using conventional EMS, microRNA, and T-DNA approaches (Lemieux et al., 1990; Okuley et al., 1994; Song et al., 2010; Belide et al., 2012). The recent development of CRISPR/Cas9 facilitated the effective elimination of the \textit{FAD2} function in a targeted manner (Jiang et al., 2017; Do et al., 2019; Yuan et al., 2019; Bahariah et al., 2021). However, CRISPR/Cas9 induces DSBs and relies on the endogenous DNA repair process, i.e., NHEJ, to generate indels, which most frequently yield \textit{FAD2} KO alleles, and thus make them unsuitable to field cultivation due to their growth defects. In this study, we aimed to combine the advantage of using CRISPR/BEs with a traditional “forward genetics” approach by randomly applying BEs to select genomic regions to induce missense mutations and then screen for candidate alleles with desirable phenotypes. Our “proof-of-concept” study reveals several advantages over conventional approaches, such as TILLING as follows: (1) much smaller size of screening population is required due to strategic targeting of mutagenic BEs within only select genomic regions; (2) a broader variety of point mutations can be induced, including not only base transitions, such as C-to-T and A-to-G but also...
FIGURE 4 | Analyses of physiological responses of “attenuated” fad2 alleles. (A–C) Germination tests for fad2 alleles conducted in (A), 1/2 MS, (B), 1/2 MS, 150-mM NaCl, and (C), 1/2 MS; 300-mM Mannitol condition to test whether increases in oleic acid content influence germination under both normal and stress conditions. The pictures were taken after 96 h of sowing. Germination rates were measured every 12 h in triplicate. (D–F) Analyses of root growth rates of fad2 alleles, whose seedlings had been grown for 4 days in 1/2 MS and then were transferred to both normal and stress conditions to allow root development for 5 days. The data presented in (D), pictures taken to identify root lengths of 5-day-grown seedling under experimental conditions, (E), graphs indicating the root lengths in different conditions, and (F), a graph showing relative root lengths in 75-mM NaCl and 200-mM Mannitol when the root length in 1/2 MS was set to 100%. All values represent mean ± SD.

FIGURE 5 | Alignment of FAD2 amino-acid sequences among Arabidopsis and various oil crops. Protein alignment was conducted by ClustalW in the MEGA7 program focusing on the g5 region in this study. The red box indicates the base editing window in this study. At, Arabidopsis thaliana; Ca, Corylus avellana; Ec, Eucalyptus camaldulensis; Gm, Glycine max; Os, Oryza sativa; Pl, Physarum ferdlerii; Rc, Ricinus communis; Zm, Zea mays. Different colors of amino acid are based on the polarity of the R group.

C-to-G base transversions, some of which are not feasible using EMS mutagenesis; and (3) combinatorial cis mutations within a narrowly defined region can be obtained, as seen in fad2-144 (A295G; D298E) and fad2-321 (A295V; T296M). Furthermore, the results imply that our proposed “semi-random” mutagenic approach, particularly when combined with high-throughput
gRNA library screening methods (Jae-Young et al., 2019), may offer a novel complementary platform for plant molecular breeding.

**DATA AVAILABILITY STATEMENT**

The original contributions presented in the study are included in the article/Supplementary Material, further inquiries can be directed to the corresponding authors.

**AUTHOR CONTRIBUTIONS**

M-EP, J-YY, and HUK performed the experiments, analyzed the data, and wrote the manuscript. All authors have read and approved the final manuscript.
