Abstract

The COVID-19 (coronavirus disease-19) has resulted in nationwide lockdowns, cessation of school and work, and social distancing. Reducing the negative impacts, such as weight-gain, has garnered global attention. In this dual-center prospective cohort study of 12,889 students, we assessed weight-gain in a youth during the 4-month COVID-19 lockdown, and examined the associations between weight-gain and COVID-19 induced stress, depression and self-reported physical activity, dietary habits and sedentary time. Participants gained an average of 2.6 kg (95% CI: 2.0 to 3.2 kg) for males and 2.1 kg (1.9 to 2.4 kg) for females. An increase in overweight and obese individuals as a demographic percentage by 4.5% and 2.7% and 4.8% and 3.4% in males and females respectively (P<0.001). Weight change was independently associated with severe COVID-19 induced stress, sedentary time, and depression score. Techniques to relieve COVID-19 induced stress, reduce sedentary time through increased physical activity, and improve dietary habits in youth may be warranted to help prevent and/or reverse weight-gain associated with the lockdown period of COVID-19.

Registration: Registered with ChiCTR, registration no.: ChiCTR2000033514
Introduction

The sudden emergence of COVID-19 (coronavirus disease-19) has reverberated the world over, pushing peoples and governments into the unchartered territories of countrywide lockdowns and social distancing. On January 20, 2020, China issued a national lockdown as a measure to halt the spread of the deadly virus. While this strategy was largely successful, its negative effects will be of consequence to the health of youth, as for four months they were out of school and for the most part, stuck in the confines of their homes. With these lockdowns comes the possibility of weight change that may be associated with amplified stress, depression, anxiety, sedentary time, unhealthy dietary habits, and more, reducing the negative impacts of lockdown on the general public has attracted global attention.

Weight-gain compared to stable weight during adolescence and early adulthood is associated with a significantly increased morbidity of diabetes and cardiovascular disease, and an increased risk of cardiovascular and all-cause mortality. The increase of weight is a multifactorial matter, yet existing evidence on these factors is largely limited due to a tendency in studies to do a univariate analysis of behaviours on weight-gain. Furthermore, trials that focus on weight loss tend to enlist already obese subjects and intervene with specialized diets attenuating short-term weight loss, limiting the extrapolation of the findings to other populations. Notwithstanding, long-term observational studies have found dietary factors, and time spent watching TV were associated with long-term weight-gain in healthy populations. To date, no
studies have been published relating to weight change and its associated factors during the COVID-19 lockdown period.

This dual-center prospective cohort study assessed weight change during the pandemic lockdown through a multifactorial analysis of associated exposure variables. This study is important because it will help identify factors that could be helpful in the prevention and/or reversal of weight-gain during community-wide shutdowns, such as the ongoing COVID-19 pandemic.
Methods

Study design and participants

This prospective cohort study enrolled youth from two universities (Hunan Traditional Chinese Medical College, Hunan, China, and Medical College of Jinhua Polytechnic, Zhejiang, China) that performed the Chinese National Student Physical Fitness Standard (CNSPFS) battery between December 1, 2019, to January 20, 2020, when the government issued sanctioned lockdowns and social distancing. A total of 14,059 university students who were free of chronic diseases and had completed the CNSPFS were screened. Of these, 13,013 participants (response rate of 93.2%) completed a follow-up online questionnaire beginning on May 1, 2020, and ending on May 23, 2020. The participants who replied with questionnaires of poor quality were excluded (n = 124). A total of 12,889 participants were finally recruited in the study. All baseline data were extracted from the CNSPFS system, follow-up data were collected from a professional survey platform (https://www.wjx.cn). The criteria of poor quality were: (1) ID information in the CNSPFS system did not match that in the follow-up questionnaire; or (2) The 81 question survey was completed in less than three minutes.

Characteristics of Lockdown

The first lockdown order in China was delivered on January 23rd, 2020 by the government of Wuhan, Hubei province, followed by the other cities and provinces of China. The main requirements included: (1) all individuals were ordered to stay home
or at their place of residence, except for permitted work, local shopping or other permitted errands, or as otherwise authorized. (2) all schools, sports facilities, entertainment, and recreational venues, personal care and beauty services, and the majority of factories and markets were closed.

Weight change

Baseline weight was assessed by staff members of the two respective universities. This was done in accordance with CNSPFS standards for all university students across China. Follow-up body weight was obtained via questionnaire. Concerning the determination of follow-up body weight, all participants were asked to measure their body weight in the morning right after waking up, in a state of fasting, shoes off, no large coat. Weight change was calculated by subtracting baseline weight from follow-up weight and the results were verified according to perceived weight change. Weight change was further classified as no significant change (-0.9 to 0.9 kg), mild decrease (-3.9 to -1.0 kg), moderate decrease (-6.9 to -4.0 kg), major decrease (≤ -7.0 kg), mild increase (1.0 to 3.9 kg), moderate increase (4.0 to 6.9 kg), major increase (≥ 7.0 kg).

COVID-19 induced stress, depression and anxiety

The question used to measure COVID-19 induced stress was designed based on previous research: How concerned are you about yourself, or family members/friends being infected by COVID-19? To which the possible answers were: None; Mild;
Moderate; Major; Severe. Two psychological indexes were also used, Becks’ Depression Inventory, second edition (BDI-II)\(^6\) and the State-Trait Anxiety Inventory (STAI) (Form Y-1).\(^7\)

**Physical activity**

Physical activity was classified as exercise and free-living activity. Exercise habits were collected through questions regarding exercise pre- and post-lockdown, these included frequency, duration, and intensity of aerobic exercise as well as strength exercise. Exercise volume was expressed in MET-hr/wk, calculated according to the American College of Sports Medicine (ACSM) metabolic equations prior to and during the lockdown.\(^8\) Sedentary time, defined as any waking behaviour where energy expenditure is \(\leq 1.5\) MET’s while reclining or sitting, included the number of hours a day spent using a computer or mobile phone.\(^8\)

**Dietary habits**

In this study, food composition was not assessed due to the high participant burden of such a questionnaire and data collection limitations. The present study evaluated the dietary habits, including breakfast and lunch frequency, alcoholic drinks per week, and snacking times per day. Breakfast and lunch were categorized into three groups: less than once a week, two to six times per week, every day. Snacking was also categorized into three groups: no snacking, snacking once a day (day or late-night), snacking twice per day (day and late-night). Alcohol habits were recorded as the
number of drinks, one drink was defined as drinking 100 ml wine or liquor, or 1 glass/bottle/can of beer.

**Statistical analysis**

The primary outcome (dependent variable) of the present study was weight change over the lockdown, the independent variables were COVID-19 induced stress, depression, anxiety, physical activity, and dietary habits. Paired t-test and Wilcoxon signed-rank test were used for assessment in mean difference between baseline and follow-up of continuous and ordinal variables respectively. The independent relationships of COVID-19 induced stress, depression, anxiety, physical activity, and dietary habits to weight changes within the lockdown, using multivariable linear or binary logistics regression models and accounting for within individual repeated measures were assessed accordingly. Potential nonlinear effects of decreases versus increases in each variable were evaluated by modelling changes in indicator categories, with “no change” as the reference. Multivariable models were used to adjust for sex, age, baseline weight, physical activity, dietary habits, and psychological status simultaneously. To minimize confounding from geolocation and baseline overweight/obesity, university- and BMI-stratified multivariate linear regression were used. Additionally, results were analyzed as relative weight changes (percent), and weight change was a binary variable (weight-gain versus weight loss). Analyses were carried out with the use of SAS software, version 9.4 (SAS Institute), a two-tailed alpha level of 0.05 was considered significant.
Results

Demographics and Weight-gain

Demographics of 12,889 participants aged 19 ± 1 are presented in Table 1. Female subjects were proportionally a larger percentage of the population, which is due to subjects being selected from medical schools largely populated by females. The average weight-gain across the universities was 2.6 (95% CI, 2.0 to 3.2) kg for males and 2.1 [1.9 to 2.4] kg for females, while across sex was 4.2% of baseline body weight. There was a significant increase in overweight and obese individuals as a percentage of the population by 4.5% and 2.7% and 4.8% and 3.4% in males and females respectively. None of the participants of the study were infected with COVID-19. More details are shown in Figure 1 A-E and supplementary Table 1.

COVID-19 induced stress, depression and anxiety

More than one-third of all participants (34.6% of males and 42.4% of females) suffered COVID-19 induced stress in different degrees, and 6.9% of males and 7.4% of females responded to having severe stress. There was a significant difference in severe COVID-19 induced stress between males and females ($P<0.001$). The depression score obtained from BDI-II were 5 ± 8 (mean ± SD) and 6 ± 8 in males and females respectively. The anxiety score using STAI was 39 ± 10 both in males and females. More details are shown in Supplementary Table 2.

Dietary habits
Males (1.8 ± 2.9 drinks) drank more than females (0.7 ± 1.6 drinks), the mean difference and 95% CI was 1.2 [1.1 to 1.3]. In contrast, the proportion of females who ate snacks at least once per day was greater than males (females vs. males, 87.9% vs. 83.2%, P<0.001). Only 33.9% of males and 32.2% of females had breakfast every day, no significance was found across sex (P = 0.19). In contrast, 98.4 % of males and 98.6% of females had lunch every day. More details are shown in Supplementary Table 2.

Changes in physical activity

Exercise volumes per week before lockdown were 14.0 ± 12.3 and 8.9 ± 8.3 MET-hr/wk in males and females respectively. There was a mild decrease in males (mean [95% CI], -0.6 [-1.1 to -0.1]) and increase in females (2.5 [2.3, 2.7]). Sedentary times before lockdown were 6.9 ± 3.3 and 7.3 ± 3.4 hr/day in males and females respectively. There were significant increases in sedentary time both in males (3.9 [3.7 to 4.1]) and females (3.6 [3.5 to 3.7]). More details are shown in Figure 1F and G, and Supplementary Table 1.

Relationships of COVID-19 induced stress, depression and anxiety to weight change

After multivariable adjustment, COVID-19 induced stress was independently related to weight-gain. Compared with those without stress, male and female subjects who suffered severe stress gained 0.88 [0.15 to 1.61] kg in males and 0.49 [0.13 to 0.82] kg in females. After stratification for BMI < 24 and ≥ 24 kg/m², two universities, and
in analyses when evaluating weight change as an absolute and relative weight change, and as a binary variable (weight gain versus weight loss) the results remained consistent (Table 3, Figure 2 A-C, Supplementary Table 3-5). However, the weight of the subjects whose stress is between mild-major had no statistical significance. Depression score was also independently associated with weight change in males (0.02 [0.01 to 0.05] kg) and females (0.02 [0.01 to 0.03] kg). Across quartiles, participants with a greater increase in depression score gained 0.14 kg more (Figure 2B). There is a significant relationship between anxiety and weight change in females (0.01 [0.01 to 0.02] kg), but not in males (0.01 [-0.01 to 0.03] kg).

**Relationships between changes in physical activity and weight change**

Sedentary time was independently related to weight change in males (0.53 [0.49 to 0.57] kg) and females (0.46 [0.45 to 0.48] kg). Findings were comparable, in direction and magnitude, for males and females, after stratification for BMI < 24 and ≥ 24 kg/m², and two universities (Table 3, Figure B and C, Supplementary Table 3-5). Concerning exercise volume, after age and weight adjustment analysis, weight change was negatively associated with an increase in exercise volume in females alone (-0.007 [-0.014 to -0.000] kg). Categorical analyses of sedentary time revealed similar linear relationships that is, aggregate change in sedentary time was robustly related to weight-gain in a dose-dependent fashion, with a 1.56 kg greater weight-gain across quartiles (Figure 3).
**Relationships between dietary habits and weight change**

When adjusted for age and baseline weight, snacking frequency per day was positively related to weight change only in females (0.46 [0.21 to 0.71] kg); alcohol drinks per week was positively associated with weight change in males (0.03 [0.2 to 0.8] kg), but negatively associated in females (-0.07 [-0.12 to -0.03] kg). In addition, breakfast frequency per week was positively related to the weight-gain only in females (0.81 [0.54 to 1.09] kg), lunch breakfast frequency per week only in males (1.52 [0.19 to 2.85] kg). However, after multivariable adjustment, no significant associations were between weight change and dietary habits (not shown).

**Additional Analyses**

All results were similar when evaluated as relative (percent) weight changes rather than absolute weight changes, and when weight change as a binary variable (weight-gain versus weight loss) (Table 3, Figure 2 A-C, Supplementary Table 3-5). Correlations of COVID-19 induced stress to DBI-II depression score, STAI anxiety score, physical activity and dietary habits were generally small (r<0.05).

**Discussion**

This is the first prospective multivariate analysis aimed at exploring the burden of imposed lockdowns practices on weight-gain. Longitudinal studies have shown that the average yearly weight-gain in general populations is approximately 0.45 kg a year. This study has found that over a 4-month lockdown period there was significant
weight-gain in the cohort, an average increase of 2.2 [2.2 to 2.3] kg, and an increase in overweight and obese individuals as a percentage of the population by 4.8% and 3.3% respectively across sexes in youth (P<0.001). Sharp increases in weight have been associated with an increase in blood pressure. Even more moderate increases over a longer period of time are associated with chronic diseases, all of which are exacerbated when weight is gained during adolescence and youth to have later life repercussions. In this study, severe COVID-19 induced stress was significantly associated with weight-gain during the lockdown period, as were other factors to a lesser degree, including change in sedentary time, depression, and dietary habits.

Evidence has been accumulating that lockdown conditions have increased the prevalence of depression, anxiety, and stress across multiple populations. The present study found that severe stress over COVID-19 was associated with a 0.49 [0.13 to 0.82] kg and 0.88 [0.15 to 1.61] kg gained weight in females and males respectively. Stressful life events, such as university/school-related stress are known to be associated with weight-gain. Additionally, instances of high to extreme levels of stress can influence eating behaviours, a factor which is more evident with higher severity of stress. Additionally, stress is thought to affect PA also, a comprehensive review found the majority of 55 longitudinal studies supported an association between stress and lower levels of PA. However, in our study the correlation between stress and changes in PA or dietary habits was quite low (r<0.05). Nevertheless, the mechanism behind this remains unknown and out of the scope of this research.
Furthermore, social isolation and confinement are possible routes towards depression.\textsuperscript{18} Our results may be due in part to the interplay between social isolation and depression on weight, as reflected by our findings that BDI-II depression score was associated with increased body weight in males (0.02 [0.01 to 0.05] kg) and females (0.02 [0.01 to 0.03] kg). This is in agreement with a consortium of previous studies, whereby depression appears to have a significant effect on short-term and long-term weight-gain.\textsuperscript{19,20} The pathways thought to be responsible for this association, may be the adoption of less healthy eating patterns, such as the excessive intake of carbohydrate-rich foods, or to a lack of motivation towards activities that require physical effort such as exercise or sport.\textsuperscript{19,21} In this study anxiety was a minimal contributor to weight-gain in females, but not males (Table 2). Anxiety during the lockdown also appears to be more commonly present in females rather than males, which supports previous studies that during the pandemic state anxiety appears to affect females more than males.\textsuperscript{22}

Energy balance and therefore weight-gain is heavily mediated through physical activity. Increased levels of PA, whether as exercise or free-living PA will accordingly increase energy expenditure, any decrease in such will likewise decrease energy expenditure.\textsuperscript{23} As an indicator of free-living PA, sedentary time was found to be associated with increased weight, accounting for an average of 0.53 [0.49 to 0.57] kg weight-gain in males and 0.46 [0.45 to 0.48] kg in females. These findings are consistent with prior research showing sedentary behaviour, TV viewing and
computer use being risk factors for increased weight.\textsuperscript{24,25} Sedentary behaviours comprise of very little calorific demand.\textsuperscript{26} Therefore, they are often the focus of weight loss interventions, as treatment studies have shown that decreases in sedentary times are associated with decreased body fat and weight. Moreover, sedentary time is particularly adverse in the absence of occupational or social cues.\textsuperscript{27} Thus, this would be exacerbated during the COVID-19 pandemic and subsequent country-wide lockdown, whereby the populations affected would have limited exposure to outdoor activities, would be out of school or work, and would be generally restricted to their homes.

Furthermore, in the present paper, self-reported exercise volume decreased modestly in males and increased in females (Figure 1F). The univariate analysis demonstrated that exercise volume was modestly associated with weight change in females alone (\(-0.007 [-0.014 \text{ to } -0.000] \) kg), possibly due to the low exercise volume both before (14.0 and 8.8 MET-hr/wk in males and females) and during lockdown (13.4 and 11.3 MET-hr/wk) far below the ACSM-recommended exercise volume (16.7 MET-hr/wk),\textsuperscript{8} and change in exercise volume across sexes being small. Various studies have looked into free-time and PA. While there is some disagreement within population cohorts, in university students it appears that exercise habits are largely mediated by time constraints,\textsuperscript{28} where students perceive limited time as a primary reason for not exercising. Also, adherence to exercise is often extrinsic, particularly in youth, where exercisers do so because of physical appearance, weight-gain and stress.
management adding plausibility that exercise may have been increased as management for perceived weight-gain and/or stress and due to more available time. Weight-gain also comes through increased intake of calorie-rich food, large portions and dependent on food composition\textsuperscript{29} leading to weight-gain. Although this study did not report on dietary composition, it did investigate dietary habits using four parameters, namely: snacking, breakfast, and lunch frequency and alcohol intake. When adjusted for age and baseline weight, snacking frequency per day was positively related to weight change in females alone (0.46 [0.21 to 0.71] kg); while alcohol drinks per week was positively associated with weight change in males (0.03 [0.2 to 0.8] kg), but negatively associated in females (-0.07 [-0.12 to -0.03] kg). Moreover, breakfast frequency per week was positively related to the weight-gain only in females and lunch breakfast frequency per week in males only. However, after multivariable adjustment, no significant associations remained between weight change and dietary habits.

Limitations
Just as with any medical intervention or organic finding, the results here represent the average public effect, and variations within individuals exist. The present cohort study only followed up the 4-month lockdown that resulted from the COVID-19 pandemic, and largely comprised Han, university-educated Chinese youth, which potentially limits the generalizability of the findings. However, our findings were consistent among two universities, sex, and individuals with BMI < 24 and ≥ 24 kg/m\textsuperscript{2}, with
multivariable adjustment of age, baseline weight, change in physical activity, dietary habits, psychological status, smoking status. All results remained persistent in additional analyses when evaluated weight change as relative (percent) weight changes rather than absolute weight changes, and when weight change as a binary variable. It seems plausible that the biologic effects of many factors would be qualitatively similar in other populations.

**Conclusion**

Severe COVID-19 induced stress, depression, and sedentary time was independently associated with weight-gain during a 4-month lockdown period related to the COVID-19 pandemic. These findings suggest that strategies to improve lifestyle habits and psychological health are warranted to mitigate COVID-19 induced stress and its associated adverse weight-gain.

**Authors contributions**

SXL, YSD and JWR conceived the study. SXL and YSD were involved in securing funding for the study. NJZ, BYY, WLZ, YCD, JL, HL and QXL coordinated the study conduct and data collection. YSD and SYX did the study analyses, supervised by SXL. YSD and JWR wrote the article, with assistance from RJT, TPO, BYY, QXL, HL and SXL. All authors approved the final version of the manuscript. SXL had full access to all the data in the study and had final responsibility for the decision to submit for publication.
Funding

This study is supported by Hunan Development and Reform Commission Foundation of China (No. [2012]1521 to SXL) and The Youth Science Foundation of Xiangya Hospital (Grant number 2019Q03 to YSD).

Competing interests

No potential conflicts of interest relevant to this article were reported by any of authors.

Ethical approval

This study received ethical approval from the Medical Ethics Committee of Xiangya Hospital, Central South University (REC reference: 202005126). All participants gave consent before enrolment in the study, which was conducted in accord with the principles of the Declaration of Helsinki.

Data Sharing Statement

The data that support the findings of this study are available on request from the corresponding author, SXL. The data are not publicly available due to their containing information that could compromise the privacy of research participants.

Transparency

The manuscript’s guarantor (SXL) affirms that the manuscript is an honest, accurate, and transparent account of the study being reported; that no important aspects of the
study have been omitted; and that any discrepancies from the study as planned (and, if relevant, registered) have been explained.

**Brief statements of assistance**

We would like to thank all participants and investigators in participating centers. We would also like to thank Jiabi Qin and Jing Deng (Xiangya School of Public Health, Central South University, Hunan, China), who provided advice on the statistical analysis plan.

Multivariable model was used to adjust for sex, age, baseline weight, the change in exercise volume, dietary habits (including breakfast and lunch frequency per week, and snacking frequency per day), alcohol, smoking, anxiety score, and all the variables shown in the table simultaneously. Mean variance inflation factors were 1.14, 1.15, and 1.15 for males, females and total analyses respectively. Data were expressed as weight change associated with increase in sedentary time and depression score.

¶ For COVID-19 induced stress, no stress was a reference.
Figure 1. Changes in body weight (A), body mass index (B), proportion of overweight and obesity (C), gained weight as a proportion in males (D) and females (E), exercise volume per week (F), and sedentary time per day (G) over the 4-month lockdown.
Line indicates mean, and error bar indicates standard deviation. Mean difference and 95% confidence interval.
Figure 2. (A) The relationship between COVID-19 induced stress and weight change, 

\( P < 0.001 \) for comparison between no stress and severe stress were. (B) The relationship between the cross-stratified quartiles of changes in sedentary time and depression score in ascending order with weight changes. As compared with individuals in the lowest quartiles of both sedentary time and depression score, individuals in the highest quartiles had a 5.82 kg greater weight-gain \( (P < 0.001; 95\% \text{ CI, 5.37 to 6.27}) \). There was no significant interaction between sedentary time and depression score \( (P = 0.92) \). All weight changes were adjusted for sex, age, baseline weight, change in exercise volume per week, dietary habits (including breakfast and lunch frequency per week, and snacking frequency per day), alcohol, smoking, anxiety score, and all the variables shown in the figure simultaneously. (C) Multivariable model was used to adjust for sex, age, baseline weight, change in exercise volume, dietary habits (including breakfast and lunch frequency per week, and snacking frequency per day), alcohol, smoking, anxiety score, and all the variables shown in the table simultaneously. Mean variance inflation factor was 1.15.
(n = 9,108 subjects with weight-gain, 2,618 with weight loss). $P < 0.001$ for all comparisons.
