Abstract
We report an eight year female patient admitted to the department of pediatrics at Abbasis Pulmonary Hospital at Cairo, Egypt. The child was complaining of pain on the right lower chest and upper abdomen. On evaluation by CT of the chest, there was a huge posterior mediastinal mass occupying more than three quarters of the right hemithorax. Preoperative histopathology using CT guided needle biopsy revealed ganglioneuroma. The tumor was resected completely via right standard postero-lateral thoracotomy without complications. Postoperative histopathology confirmed the diagnosis of ganglioneuroma.

Keywords: Ganglioneuroma; Posterior mediastinum; Pediatrics

Introduction
Gangioneuromas are rare benign neurgenic tumors which arises from neural crest cells that represents the final maturation stag of neuroblasts [1]. The incidence of ganglioneuroma was reported to be 1 in 1,000,000 and thought to develop de novo rather than by maturation of existing neuroblastoma [2]. There are no known risk factors, however the tumors may be associated genetic problems, such as neurofibromatosis type 1[3]. Ganglioneuromas are commonly classified as pediatric mediastinal tumors occurring in females more than males with a ratio about 3 : 1 [4]. Most of the cases are asymptomatic and usually discovered accidentally. The most common sites of ganglioneuromas are the posterior mediastinum and retroperitonium (37.5% each) [5]. Surgical resection of mediastinal ganglioneuroma is the treatment of choice [6]. The aim of this report is to present a case of ganglioneuroma in an eight years old female, to show its mode of presentations, different preoperative tools used for the diagnosis and the standard line of treatment in such cases which is complete surgical resection.

Case Report
Female child 8-years old presented with her mother to the outpatient clinic of the pediatric department at Abbasis Pulmonary Hospital, Cairo governorate, Egypt. The child was complaining of repeated right sided chest pain. The pain started 4 months before presentation to our hospital, the pain is sharp in character and mild in intensity. The pain was affecting the lower part of the right chest, and sometimes referred to the upper abdomen. The pain is on and off in character and each times lasts about one minute or two. The pain had no aggravating or relieving factors. There was no history fever, weight loss no GIT symptoms or other respiratory symptoms. The history of the pregnancy given by her mother was normal with vaginal delivery. Also, all the child developmental milestones were normal. Family history and consanguinity were negative. A plain chest X-ray P-A view was done in the outpatient clinic that revealed a huge well circumscribed, radio opaque, homogenous posterior mediastinal mass (Figure 1). So the child was admitted to the pediatric department for further evaluation.
Figure 1: Chest X-ray P-A view showing.
Giant opacity occupying most of the right hemithorax.

General examination of the child was unremarkable. Chest examination revealed decreased air entry on the right back of the chest with scattered rales. All laboratory investigations were within normal level. CT scan of the chest was done (Figures 2&3) and revealed a giant, non enhancing about 20 X 23 cm well-defined, more or less rounded mass which is homogenous and non-enhancing. The mass was located on the right hemithorax in the posterior mediastinum. The mass was abutting the thoracic vertebrae in the paravertebral gutter. CT guided needle biopsy was taken and histopathology report revealed a ganglioneuroma. After histopathological diagnosis, the patient was referred to the Thoracic surgery department at our hospital for surgery. Surgical resection of the tumor was performed by a team of thoracic and neurosurgery via right slanted posterolateral thoracotomy in the fifth space. During surgery the tumor was found to be well encapsulated with firm consistency, well circumscribed not invading any nearby structures. Due to the huge size of the tumor, it was resected in two pieces (Figure 4). During operation there was considerable bleeding, so interaoperative embolization of the feeding vessels that stopped the bleeding. The weight of the tumor was 830 gm (Figure 4). Postoperative histopathology confirmed that the tumor was benign ganglioneuroma. The patient had uneventful postoperative course and was discharged from the hospital after 10 days in good condition for regular follow up.

Ganglioneuroma are rare benign tumors of the autonomic nerve fibers arising from the neural crest sympathogonia. Ganglioneuromas are fully differentiated neuronal tumors that do not contain immature elements. They are typically well encapsulated tumors with a fibrous capsule that arise in the posterior mediastinum [7]. Our case showed a well encapsulated tumor during surgery. Ganglioneuromas occur most commonly in young patients, however they may be found in adult life. They represent the most common tumor arising in the posterior mediastinum in pediatric age group [8]. Our case was a child of 8 years old with a posterior mediastinal ganglioneuroma. Ganglioneuromas are mostly asymptomatic and are known as pediatric intrathoracic incidentoma. They are discovered when the patient is assessed for another disease [9]. Symptoms of the tumor depends on its site and compression effect on the adjacent structures. So, symptoms of mediastinal may include shortness of breath, chest pain or Horner’s syndrome if it compressing the sympathetic ganglia. Retroperitoneal ganglioneuroma may cause abdominal pain and bloating. Compression of the spinal cord by

**Discussion**

Ganglioneuroma are rare benign tumors of the autonomic nerve fibers arising from the neural crest sympathtogonia. Ganglioneuromas are fully differentiated neuronal tumors that do not contain immature elements. They are typically well encapsulated tumors with a fibrous capsule that arise in the posterior mediastinum [7]. Our case showed a well encapsulated tumor during surgery. Ganglioneuromas occur most commonly in young patients, however they may be found in adult life. They represent the most common tumor arising in the posterior mediastinum in pediatric age group [8]. Our case was a child of 8 years old with a posterior mediastinal ganglioneuroma. Ganglioneuromas are mostly asymptomatic and are known as pediatric intrathoracic incidentoma. They are discovered when the patient is assessed for another disease [9]. Symptoms of the tumor depends on its site and compression effect on the adjacent structures. So, symptoms of mediastinal may include shortness of breath, chest pain or Horner’s syndrome if it compressing the sympathetic ganglia. Retroperitoneal ganglioneuroma may cause abdominal pain and bloating. Compression of the spinal cord by

ganglioneuroma may cause motor or sensory loss in the legs, arms or both or spinal deformity [10]. Such tumors may produce certain hormones which can cause diarrhea, enlarged clitoris in women, high blood pressure or sweating [11]. Our case was a posterior mediastinal tumor that presented with right sided lower chest pain which was referred to upper abdomen.

Radiological studies are very useful tools in suggesting the diagnosis of posterior mediastinal ganglioneuroma. Plain X-ray postero-anterior and lateral views show the posterior mediastinal mass well delineated mass that may cause rib spreading and foraminal erosion. CT scan of the chest shows well circumscribed mass which are iso to hypoattenuating to muscle. The tumor may show calcifications in 20% of tumors. The calcifications are typically fine and speckled but may be coarse. MRI also is a useful radiologic modality in diagnosis of mediastinal ganglioneuroma. Mediastinal ganglioneuroma on imaging should be differentiated from cystic teratoma, neurilimmoma, lymphangiom cysticum or bronchocele [12]. The standard treatment of mediastinal ganglioneuroma is surgical excision especially when there are symptoms of compression, marked increase in size or encroaching on the vertebral foramina [13].
