'Wallpaper paste sign' of mucinous breast carcinoma

Muhammad Asad Parvaiz, Brian Isgar, Nedra Aluwihare

ABSTRACT

Introduction: Mucinous carcinoma of the breast is an uncommon disease, characterized by a large amount of mucin production. Histologically, it is classified into two subgroups—pure type and mixed type. It usually affects postmenopausal women and is commonly associated with good prognosis. Case Report: We present a case of a 53-year-old female with a palpable breast lump which was clinically as well as radiologically suspicious of breast cancer. A free-hand needle core biopsy was carried out. The biopsy material retrieved had a distinctive gross appearance, with soft, gelatinous consistency and a glistening clear surface. On this typical macroscopic appearance, a diagnosis of 'mucinous breast carcinoma' was made, which was subsequently confirmed on histological examination. The typical gross appearance of specimen on needle core biopsy is similar to the appearance of wallpaper paste; hence we describe it as 'wallpaper paste sign'. Conclusion: The hallmark of mucinous carcinoma is extracellular mucin production that gives it a typical glistening macroscopic appearance. Keeping in mind the 'wallpaper paste sign' we describe, mucinous breast carcinoma can be diagnosed on patient’s first visit to the breast clinic on gross inspection of the needle core biopsy specimen.

Keywords: Mucinous breast carcinoma, Wallpaper paste sign, Extracellular mucin, Core biopsy

INTRODUCTION

Mucinous carcinoma of the breast is not a common disease and its incidence has been reported to range from 1–6% of all primary breast cancers [1–4]. It is characterized by a large amount of mucin production and in general, defined as having a mucinous component of 50% or more [5, 6]. Histologically, it is classified into two subgroups—pure type and mixed type [7, 8]. The pure type is the classical type composed entirely of mucinous carcinoma and can be further subdivided into cellular and hypo-cellular variants based on the degree of cellularity. When the mucinous component is mixed with another tumor type, this is the condition of mixed mucinous cancer which is most commonly ductal type (mucinous-ductal).

Immunohistochemistry is not generally required for the confirmation of mucinous breast carcinoma. However, a notable proportion of lesions especially the cellular variant of pure mucinous carcinoma demonstrate neuroendocrine differentiation. These tumors are immunoreactive for chromogranin and synaptophysin [5, 9]. Typically, mucinous carcinoma is estrogen receptor positive.
CASE REPORT

A 53-year-old female was presented to the breast clinic with a palpable breast lump. Clinically, the lump was suspicious of breast cancer. Mammogram and ultrasound scan also confirmed the suspicious nature of the lump. A free hand needle core biopsy was carried out in the one-stop triple assessment clinic on index presentation. The core biopsy material retrieved had a distinctive gross appearance, with soft, gelatinous consistency and a glistening clear almost see-through surface (Figure 1). On this typical macroscopic appearance, a diagnosis of ‘mucinous breast carcinoma’ was made, which was subsequently confirmed on microscopic histological examination. The hallmark of mucinous carcinoma is extracellular mucin production, the extent of which varies from tumor to tumor. Typically, mucinous cancer cells in small clusters, sheets, or papillary configurations are dispersed within pools of extracellular mucin (Figure 2).

DISCUSSION

Mucinous carcinoma of the breast usually occurs in postmenopausal women. Median age of diagnosis is 71 years (range 25–85 years) [4, 6]. It shows more favorable clinicopathological characteristics, such as lower incidence of nodal metastasis, higher expression of estrogen and progesterone receptors and differentiated grade [2, 6, 10, 11].

The typical gross appearance of the mucinous breast carcinoma is a well-defined cystic mass, consisting of abundant transparent to bloodstained mucin as well as whitish solid parts [12]. This gelatinous and glistening gross appearance of mucinous breast carcinoma on needle core biopsy is similar to the appearance of wallpaper paste used to stick the wallpaper to a wall. We describe it as ‘wallpaper paste sign’ of mucinous breast carcinoma on needle core biopsy because of this similarity in appearances. This sign has been successfully reproducible in our practice over a period of time. Whenever such needle core biopsy appearance is retrieved in the clinic, we write ‘positive wallpaper paste sign– mucinous breast carcinoma?’ on the histology request form. This has always been confirmed on the microscopic analysis and immunohistochemistry when required.

Mucinous breast carcinoma is associated with a relatively favorable prognosis with a 5-year breast cancer specific survival rate of 94%. Although slowly decreasing with time, 10, 15 and 20 years survival rates are 89%, 85% and 81%, respectively compared to 82% (5 year), 72% (10 year), 66% (15 year) and 62% (20 year) for invasive ductal carcinoma [1, 6, 13–15].

CONCLUSION

Mucinous carcinoma is relatively rare type of breast cancer and it can be diagnosed on patient’s first visit to the breast clinic on gross inspection of the needle core biopsy specimen.
