Abstract

We exhibit an algorithm to compute the strongest algebraic (or polynomial) invariants that hold at each location of a given unguarded linear hybrid automaton (i.e., a hybrid automaton having only unguarded transitions, all of whose assignments are given by affine expressions, and all of whose continuous dynamics are given by linear differential equations). Our main tool is a control-theoretic result of independent interest: given such a linear hybrid automaton, we show how to discretise the continuous dynamics in such a way that the resulting automaton has precisely the same algebraic invariants.

1 Introduction

Invariants are one of the most fundamental and useful notions in the quantitative sciences, appearing in a wide range of contexts, from gauge theory, dynamical systems, and control theory in physics, mathematics, and engineering to program verification, static analysis, abstract interpretation, and programming language semantics (among others) in computer science. In spite of decades of scientific work and progress, automated invariant synthesis remains a topic of active research, particularly in the fields of computer-aided verification and program analysis, and plays a central role in methods and tools seeking to establish correctness properties of computer systems; see, e.g., [4], and particularly Sec. 8 therein.

In this paper, we consider the task of computing strongest algebraic inductive invariants for unguarded linear hybrid automata. Hybrid automata are a formalism for describing systems or processes that combine discrete and continuous evolutions over their state variables. A hybrid automaton is therefore equipped with a finite set of real-valued variables, as well as a finite set of control location (or modes). In each location, the variables evolve according
Algebraic Invariants for Linear Hybrid Automata

to some differential dynamics. Transitions between control locations may effect discrete updates (also known as resets) to these variables. A hybrid automaton is unguarded if the transitions do not have any guards, or preconditions, in order to be fired, and it is linear if the discrete updates on the variables consist entirely of affine transformations, and the continuous dynamics within each control location are defined by linear differential equations.

An invariant assigns to each control location a fixed set of real values in such a way that through any trajectory of the hybrid automaton, the values of the variables always remain within the invariant. The invariant is inductive provided, informally speaking, that it is itself preserved by the (continuous and discrete) dynamics of the hybrid automaton. Finally, an invariant is algebraic (or polynomial) if it consists in a collection of varieties (or algebraic sets), i.e., positive Boolean combination of polynomial equalities. As it happens, the strongest polynomial invariant (i.e., smallest variety with respect to set inclusion) is obtained by taking the Zariski closure of the set of reachable configurations in each control location; such an invariant is always inductive provided that the dynamics are Zariski continuous.

There is a rich history of research into the computation of algebraic invariants for various classes of (discrete) computer programs; we refer the reader to our recent paper [3] and references therein. There has also been a substantial amount of work on algebraic invariant generation for hybrid systems, albeit in more recent years. One of the earliest pieces of work on this topic is by Rodrígez-Carbonell and Tiwari [7], who consider linear dynamical systems (i.e., linear hybrid automata with a single discrete location and no transition) and show how to compute strongest algebraic invariants for these. They then leverage abstract-interpretation techniques to derive algebraic invariants for linear hybrid automata, however without guarantees on the strength of the invariants. In [9], Sankaranarayanan et al. compute algebraic invariants for polynomial hybrid systems directly using constraint solving over template invariants (without however guaranteeing to obtain the strongest invariant). In subsequent work, Sankaranarayanan shows how to compute strongest algebraic invariants up to a fixed degree [8] for the same class of automata. Using different analytic techniques, Ghorbal and Platzer show in [2] how to compute algebraic invariants and differential invariants for polynomial hybrid automata; more precisely, they show that deciding whether a collection of algebraic sets forms an algebraic invariant is decidable; they do not however provide a procedure to guarantee that a given invariant is the strongest possible.

Main results. Our contributions in the present paper are threefold. First, for the class of unguarded linear hybrid automata, building on our recently developed invariant-generation techniques for affine programs [3], we show how to compute strongest algebraic invariants. Our main technical tools come from linear algebra, algebraic geometry, and Diophantine geometry. Second, we show how one can discretise an unguarded linear hybrid automaton in such a way that the discretised version has precisely the same algebraic invariants as the original one; we are not aware of any such result in the extant control-theoretic and cyber-physical systems literature. And third, we show that as soon as equality guards are allowed, even for the restricted class of linear switching systems, there cannot exist an algorithm for computing strongest algebraic invariants, thereby establishing clearly a hard theoretical limit on how far the work presented here can be extended.

We now provide a slightly more detailed overview of our approach and results. In Section 5 we consider a simple class of hybrid systems, with purely continuous dynamics, called switching systems. A switching system can transition arbitrarily between modes, but the variables are not reset when changing mode. It is natural to think of mode switches as being determined by an external controller which provides inputs to the system. We show that for a switching system, the Zariski closure of the set of reachable configurations is an irreducible
variety. We exploit this feature to give a conceptually simple algorithm to compute the strongest algebraic invariant of a given switching system.

In the rest of the paper we develop this basic result in two directions. In Sections 6 and 7 we generalise the above analysis to accommodate discrete transitions that may reset variables (e.g., the bouncing ball in Example 2.1 in which the velocity is reset on hitting a boundary, or the RC circuit in Example 2.2 in which the electrical currents and voltages change abruptly when a switch is turned on or off). In this setting the dynamics is not necessarily continuous. In fact, our approach here is to eliminate the continuous dynamics altogether by introducing a discretisation construction on hybrid automata that preserves all algebraic invariants. More formally, given a hybrid automaton we show how to construct a finite (discrete-time) affine program that has the same same set of variables and the same algebraic invariants as the original hybrid automaton. We can then rely on a result in [3] to compute strongest algebraic invariants.

In another direction, in Section 8 we consider the problem of computing the strongest algebraic invariant for switching systems that are augmented with the ability to test variables for zero on transitions. Here again the dynamics are exclusively continuous. We show that it is undecidable in general to compute a strongest algebraic invariant for such systems. Roughly speaking, we prove this result by defining a simulation of an arbitrary Minsky machine $C$ by a hybrid automaton $A$, such that we can effectively determine whether the set of reachable configurations of $C$ is infinite from the strongest algebraic invariant of $A$.

2 Examples

2.1 Bouncing ball

Consider a ball that bounces on horizontal slabs, as illustrated in Figure 1. The ball is moving at constant horizontal speed $c$ and is subject to gravity along the vertical axis. We assume that there is no friction and that collisions are perfectly elastic. We do not want to make any assumption on the location of the slabs, to obtain the most general system. Thus from the point of the view of system, the positions of the slabs are ‘nondeterministic’ and the slabs can ‘appear’ at any moment.

![Figure 1 A ball bouncing on horizontal slabs.](image)

We fix an arbitrary coordinate system in which the ball starts at position $(0, h)$ with initial velocities $(c, 0)$. The system is modelled using a single discrete location. There are three constants $c$ (the horizontal speed), $h$ (the initial height), and $g$ (approximately $9.8ms^{-2}$). Technically speaking we could also include $m$ (the mass of the ball), but it will not feature in the final set of invariants that we derive nor in our differential equations. There are five variables: $t$, $x$, $y$, $v_x$, and $v_y$, where $t$ is the time variable. The differential equations
are simply Newton’s laws of motion. There is a single reset with no guards modelling the action of the ball bouncing on each of the slabs (notably ensuring that the vertical velocity is instantly inverted). We obtain the hybrid system described in Figure 2a.

Now we come to the invariants. The most obvious is that the horizontal speed is constant: \( v_x = c \), which in turn entails that \( x = tc \). Next, consider an inertial coordinate system moving horizontally to the right at speed \( c \). In that system energy must be conserved. Initially there is no kinetic energy, and all the potential energy amounts to \( mgh \) (where \( m \) is the mass of the ball). At any subsequent time \( t \), the sum of the kinetic and potential energy must therefore sum to that value, i.e., \( \frac{1}{2}mv^2_y + mg(y - h) = mgh \). These must be the only invariants: the ambient space is 5-dimensional (given that our variables are \( t, x, y, v_x, \) and \( v_y \)), and the corresponding variety (with 3 equations) is two dimensional. But the system has indeed exactly two degrees of freedom, since \( t \) and \( v_y \) can be set to arbitrary values (provided \( |v_y| \leq gt \)), and once \( t \) and \( v_y \) are fixed, every other variable is fixed. In summary, the strongest algebraic invariant is the conjunction of the following three equations:

\[
v_x = c, \quad x = tc, \quad v_y^2 + 2g(y - h) = 0.
\]

### 2.2 RC circuit

Consider an RC circuit with a switch, as illustrated in Figure 3. When the switch is on, the capacitor is connected to a battery and charges. When the switch is off, the capacitor discharges through the resistor. The battery has constant voltage \( V \), the resistor has resistance \( R \) and the capacitor has capacity \( C \). There are 5 variables: the current \( I \) in the wire between the battery and the switch, the voltages \( V_R \) and \( V_C \) across the resistor and
capacitor respectively, the current \( I_R \) flowing through the resistor, and finally the charge \( Q \) held by the capacitor. All derivatives are with respect to time, though this time we choose not to include an explicit variable for the passage of time. There are two discrete locations, open and closed, corresponding to the two possible positions of the switch. We assume the switch starts in the open position. When switching from open to closed, all variables but \( Q \) and \( V_C \) experience a reset. We obtain the hybrid system described in Figure 2b.

In this example, there is one set of invariants per location. In both locations, we clearly have the invariants associated with the passive components: \( Q = CV_C \) and \( V_R = RI_R \). In the open location, we further have the invariants \( I = 0 \) and \( V_R = -V_C \). On the hand, in the closed location, we have \( I = I_R \) and \( V = V_R + V_C \). These must be the only invariants: once \( Q \) is fixed, all variables are uniquely determined. In summary, the invariants are

\[
\begin{align*}
\text{OPEN:} & \quad Q = CV_C, \quad V_R = RI_R, \quad I = 0, \quad V_R = -V_C, \\
\text{CLOSED:} & \quad Q = CV_C, \quad V_R = RI_R, \quad I = I_R, \quad V_R = V - V_C.
\end{align*}
\]

3 Mathematical Background

Let \( \mathbb{K} \) be a field. Given a set \( X \subseteq \mathbb{K}^n \), we denote by \( I(X) \) the ideal of polynomials in \( \mathbb{K}[x_1, \ldots, x_n] \) that vanish on \( X \). Given an ideal \( I \subseteq \mathbb{K}[x_1, \ldots, x_n] \), we denote by \( V(I) \subseteq \mathbb{K}^n \) the set of common zeroes of the polynomials in \( I \). A set \( X \subseteq \mathbb{K}^n \) is said to be an affine variety (also called an algebraic set) if \( X = V(I) \) for some ideal \( I \subseteq \mathbb{K}[x_1, \ldots, x_n] \). By the Hilbert Basis Theorem, every affine variety can be described as the set of common zeroes of finitely many polynomials. We identify \( \text{GL}_n(\mathbb{K}) \), the set of \( n \times n \) invertible matrices with entries in \( \mathbb{K} \), with the variety \( \{(A, y) \in \mathbb{K}^{n+1} : \det(A) \cdot y = 1\} \).

Given an affine variety \( X \subseteq \mathbb{K}^n \), the Zariski topology on \( X \) has as closed sets the subvarieties of \( X \), i.e., those sets \( A \subseteq X \) that are themselves affine varieties in \( \mathbb{K}^n \). Given an arbitrary set \( S \subseteq X \), we write \( \overline{S} \) for its closure in the Zariski topology on \( X \).

A set \( S \subseteq X \) is irreducible if for all closed subsets \( A_1, A_2 \subseteq X \) such that \( S \subseteq A_1 \cup A_2 \) we have either \( S \subseteq A_1 \) or \( S \subseteq A_2 \). It is well known that the Zariski topology on a variety is Noetherian. In particular, any closed subset \( A \) of \( X \) can be written as a finite union of irreducible components, where an irreducible component of \( A \) is a maximal irreducible closed subset of \( A \).

The class of constructible subsets of a variety \( X \) is obtained by taking all Boolean combinations (including complementation) of Zariski closed subsets. Suppose that the underlying field \( \mathbb{K} \) is algebraically closed. Since the first-order theory of algebraically closed fields admits quantifier elimination, the constructible subsets of \( X \) are exactly the subsets of \( X \) that are first-order definable over \( \mathbb{K} \).

A function \( f : \mathbb{K}^m \to \mathbb{K}^n \) is said to be a polynomial map if there exist polynomials \( p_1, \ldots, p_n \in \mathbb{K}[x_1, \ldots, x_m] \) such that \( f(a) = (p_1(a), \ldots, p_n(a)) \) for all \( a \in \mathbb{K}^m \). Recall that polynomial maps are Zariski-continuous and thus \( f(X) \subseteq f(X) \) for a polynomial map \( f \). In particular matrix multiplication is a Zariski-continuous map \( \mathbb{K}^{n^2} \times \mathbb{K}^{n^2} \to \mathbb{K}^{n^2} \).

Given a complex variety \( V \subseteq \mathbb{C}^n \), the intersection \( V \cap \mathbb{R}^n \), which is a real variety, can be computed effectively. Indeed if \( V \) is represented by the ideal \( I \subseteq \mathbb{C}[x_1, \ldots, x_n] \), then \( V \cap \mathbb{R}^n \) is represented by the ideal generated by \( \{p_R, p_I : p \in I\} \) where \( p_R \) and \( p_I \) respectively denote the real and imaginary parts of the polynomial \( p \). Given \( S \subseteq \mathbb{R}^n \), write \( \overline{S}^\mathbb{R} \) for its real Zariski closure and \( \overline{S} \) for its complex Zariski closure (i.e., we treat the complex Zariski closure of \( S \subseteq \mathbb{R}^n \) as the default). It is straightforward to verify that \( \overline{S}^\mathbb{R} = \overline{S} \cap \mathbb{R}^n \).
We are concerned with computing strongest algebraic invariants for the subclass of hybrid automata that has no guards, linear discrete updates, and linear continuous dynamics. Each location of such an automaton specifies a linear differential equation \((x' = Ax)\), and each transition between states (nondeterministic choices are allowed) specifies a linear transformation \((x \mapsto Bx)\). Such a hybrid automaton can be pictured as follows:

![Diagram of hybrid automaton](image)

Formally, such an automaton \(A\) in dimension \(d\) is a tuple \((Q, A, E, T)\), where \(Q\) is a finite set of locations, \(A = \{A_q : q \in Q\}\) is a family of real \(d \times d\) matrices, \(E \subseteq Q \times \mathbb{R}^{d \times d} \times Q\) is a set of transitions labelled by real \(d \times d\) matrices, and \(\{T_q : q \in Q\}\) is a family of algebraic subsets of \(\mathbb{R}^d\). Matrix \(A_q \in \mathbb{R}^{d \times d}\) describes the continuous dynamics at location \(q \in Q\) and \(T_q \subseteq \mathbb{R}^d\) is the set of initial states in location \(q\). We assume that the entries of all matrices are algebraic numbers and that the polynomials defining \(T_q\) have algebraic coefficients.

We will consider the subclasses of automata with the following restrictions:
- **affine programs**: \(A_q = 0\) for all \(q \in Q\), and \(E\) is finite,
- **constructible affine programs**: \(A_q = 0\) for all \(q \in Q\), and \(E\) is constructible,
- **switching systems**: \(E = \{(p, I_\alpha, q) : p, q \in Q\}\), i.e., every pair of locations is connected by an edge that does not update the variables,
- **linear hybrid automata**: \(E\) is finite.

In affine programs, variables are only updated on discrete edges: there is no continuous evolution within locations. At the other end of the spectrum, in switching systems variables only evolve continuously, and there are no discrete updates. The full class of linear hybrid automata accommodate both discrete and continuous updates to the variables.

The *collecting semantics* of \(A\) assigns to each location \(q \in Q\) the set \(S_q \subseteq \mathbb{R}^d\) of states that can occur in location \(q\) during a run of the automaton, starting from a configuration \((q, a)\) for some \(a \in T_q\). Formally, this is the smallest family (with respect to set inclusion) such that

\[
\begin{align*}
S_q &\supseteq T_q & \text{for all } q \in Q, \\
S_q &\supseteq BS_p & \text{for all } (p, B, q) \in E, \\
S_q &\supseteq e^{At}S_q & \text{for all } t \in \mathbb{R}_{\geq 0}.
\end{align*}
\]

Equivalently, let the operator \(\Phi_A : \mathcal{P}(\mathbb{R}^d)^Q \to \mathcal{P}(\mathbb{R}^d)^Q\) be defined by

\[
\Phi_A(S)_q = T_q \cup \bigcup_{t \geq 0} e^{At}S_q \cup \bigcup_{(p, B, q) \in E} BS_p.
\]

Then \(S\) is the least fixed-point of \(\Phi_A\) with respect to set inclusion. Such a least fixed-point exists because \(\Phi_A\) is monotone.

In general we say that a family of set \(\{S'_q\}_{q \in Q}\), with \(S'_q \subseteq \mathbb{R}^d\) is an *inductive invariant* if \(\Phi_A(S') \subseteq S'\), i.e., the family is pre-fixed-point of \(\Phi_A\). If each set \(S'_q\) is algebraic then we moreover say that \(\{S'_q\}_{q \in Q}\) is an *inductive algebraic invariant.*

Given \(P \in \mathbb{R}[x_1, \ldots, x_d]\), we say that the relation \(P = 0\) holds at location \(q\) if \(P\) vanishes on \(S_q\). We are interested in computing at each location \(q \in Q\) a finite set of polynomials
that generates the ideal $I_q := I(S_q) \subseteq \mathbb{R}[x_1, \ldots, x_d]$ of all polynomial relations that hold at location $q$. The real variety $V_q := V(I_q) = \overline{S_q}$ corresponding to $I_q$ is the Zariski closure of $S_q$ viewed as a subset of the affine space $\mathbb{R}^d$.

Note that the collection $V(A) := \{V_q : q \in Q\}$ defines an inductive algebraic invariant. Inductiveness amounts to the following two claims:

- for every edge $(p, B, q) \in E$, we have $BV_p \subseteq V_q$,
- for every $q \in Q$ and $t \in \mathbb{R}_{\geq 0}$, we have $e^{A_{t}q}V_q \subseteq V_q$.

The first point follows from the fact that $x \mapsto Bx$ is Zariski-continuous; the second point likewise follows from the fact that for every $t \in \mathbb{R}_{\geq 0}$ the map $x \mapsto e^{A_{t}x}$ is Zariski-continuous.

The discussion above shows that $V(A)$, the Zariski closure of the collecting semantics, is the least inductive invariant of $A$. Previously we have shown how to compute the Zariski closure of the collecting semantics of an affine program:

\textbf{Theorem 1 ([3])}. There is an algorithm that given a constructible affine program $A$ computes $V(A) = \{V_q : q \in Q\}$—the real Zariski closure of its collecting semantics.

Note that this theorem also works for (finite) affine programs since those are a particular case of constructible affine programs.

The main result of the current paper extends the above result by accommodating the continuous dynamics of hybrid automata:

\textbf{Theorem 2}. There is an algorithm that given a linear hybrid automaton $A$ computes $\{V_q : q \in Q\}$—the real Zariski closure of its collecting semantics.

5 Linear Continuous Dynamics and Switching Systems

The first step towards computing Zariski closure in the general case is to be able to handle the case of one differential equation. Write $A$ for the field of algebraic numbers. Let $A \in \mathbb{R}^{d \times d}$ and $x_0 \in \mathbb{R}^{d \times d}$, then the solution to $x(0) = x_0$, $x'(t) = Ax(t)$ is given by $x(t) = e^{At}x_0$. We are interested in computing the Zariski closure of the orbit $\{x(t) : t \in \mathbb{R}_{\geq 0}\}$. Since the map $\phi : M \mapsto Mx_0$ is Zariski-continuous, we have that

$$\{x(t) : t \in \mathbb{R}_{\geq 0}\} = \{e^{At}x_0 : t \in \mathbb{R}_{\geq 0}\} = \phi(\{e^{At} : t \in \mathbb{R}_{\geq 0}\}) = \phi(\{e^{At} : t \in \mathbb{R}_{\geq 0}\})$$

and thus it suffices to compute $\{e^{At} : t \in \mathbb{R}_{\geq 0}\}$. Furthermore, let $\mathcal{O}_A := \{e^{At} : t \in \mathbb{R}\}$, which is a commutative group. Then $\overline{\{e^{At} : t \in \mathbb{R}_{\geq 0}\}} = \overline{\mathcal{O}_A}$: the left-to-right inclusion is clear. The converse inclusion comes from the fact that an exponential polynomial (in one variable), being an analytic function, vanishes over $\mathbb{R}_{\geq 0}$ if and only if it vanishes over $\mathbb{R}$. Thus it suffices to compute $\overline{\mathcal{O}_A}$.

The following lemma gives a description of the ideal of the variety $\overline{\mathcal{O}_A}$ when $A$ is diagonal.

\textbf{Lemma 3}. Let $A = \text{diag}(\lambda_1, \ldots, \lambda_d) \in \mathbb{R}^{d \times d}$ be a diagonal matrix, then

$$\overline{\mathcal{O}_A} = \{\text{diag}(z_1, \ldots, z_d) : \forall p \in I, p(z_1, \ldots, z_d) = 0\},$$

where $I = \{z^a - z^b : a - b \in L\}$ and $L = \{n \in \mathbb{Z}^d : n_1\lambda_1 + \cdots + n_d\lambda_d = 0\}$. Furthermore, one can compute a basis for $L$ considered as an abelian group under addition.

\textbf{Proof}. Clearly $e^{At} = \text{diag}(e^{\lambda_1 t}, \ldots, e^{\lambda_d t})$. Since the set of diagonal matrices is closed, then the closure is of the form

$$\overline{\mathcal{O}_A} = \{\text{diag}(z_1, \ldots, z_n) : p_1(z) = \cdots = p_k(z) = 0\}$$
for some polynomials \(p_1, \ldots, p_k\). Thus, the ideal \(I\) of the closure is generated by all polynomials \(p\) such that \(p(e^{\lambda t}, \ldots, e^{\lambda t}) = 0\) for all \(t \in \mathbb{R}\). Let \(J\) be the ideal of all polynomials \(x^a - x^b\) with \(a, b \in \mathbb{N}^d\) such that \(\lambda \cdot a = \lambda \cdot b\). Clearly \(J \subseteq \mathcal{I}\) since if \(\lambda \cdot a = \lambda \cdot b\), then 
\[(e^{\lambda t})^{a_{1}} \cdots (e^{\lambda t})^{a_{d}} - (e^{\lambda t})^{b_{1}} \cdots (e^{\lambda t})^{b_{d}} = e^{(\lambda \cdot a)t} - e^{(\lambda \cdot b)t} = 0\] 
for all \(t \in \mathbb{R}\). Conversely, assume by contradiction that \(p \in \mathcal{I} \setminus J\) and write \(p = \sum_{i=1}^{m} b_i m_i\) for some \(b_i \in \mathcal{A}\) and monomials \(m_1, \ldots, m_r\). Further choose \(p\) so that \(r\) is minimal. For each monomial \(m_i(x) = x_1^{a_1} \cdots x_d^{a_d}\), let \(\mu_i := \lambda \cdot a_i\). Then we must have \(\mu_i \neq \mu_j\) for \(i \neq j\) because otherwise \(m_i - m_j \in \mathcal{I}\) and \(p - b_i(m_i - m_j) \in \mathcal{I} \setminus J\) would have fewer terms than \(p\). Since the maps \(t \mapsto e^{\mu_1 t}, \ldots, t \mapsto e^{\mu_r t}\) are linearly independent, it follows that \(b_1 = \cdots = b_r = 0\) which is contradiction. Thus we must have have \(I = J\). It is immediate to see that \(J\) is generated by all polynomials \(x^a - x^b\) such that \(\lambda \cdot (a - b) = 0\), thus it suffices to compute 
\(\mathcal{L} = \{a \in \mathbb{Z}^d : \lambda \cdot a = 0\}\), the set of additive relations of \(\lambda\). Notice that \(\mathcal{L}\) is an additive subgroup of \(\mathbb{Z}^d\) and as such must be finitely generated. An upper bound on the size of the elements of a basis of \(\mathcal{L}\) can be found in [5] and therefore we can compute a basis for \(\mathcal{L}\) and thus \(J, I\) and \(\mathcal{O}_A\).

A corollary of this result is that we can compute \(\mathcal{O}_A\) by separating the diagonal and nilpotent parts of \(A\). The fact that this closure is computable is not new, a similar result exists in the literature, although without proof [7].

\textbf{Proposition 4.} There is an algorithm that given \(A \in \mathbb{A}^{d \times d}\), computes \(\{e^{AT} : t \in \mathbb{R}_{\geq 0}\}\).

\textbf{Proof.} We can write \(A = P(D + N)P^{-1}\) where \(P\) is invertible, \(D\) is diagonal, \(N\) is nilpotent, and \(D\) and \(N\) commute. Notice that \(\mathcal{O}_D\) only consists of diagonal matrices and \(\mathcal{O}_N\) of unipotent matrices. Since \(\mathcal{O}_A\) is a commutative group, and \(D\) and \(N\) commute, we have that \(\mathcal{O}_A = P(\mathcal{O}_D \cdot \mathcal{O}_N)P^{-1}\), and thus \(\mathcal{O}_A = P\mathcal{O}_D \cdot \mathcal{O}_N P^{-1}\). All the operations in this equation are effective thus it suffices to compute \(\mathcal{O}_D\) as explained above, and \(\mathcal{O}_N\). But since \(N\) is nilpotent, \(q_n(t) := e^{nt}\) is really a polynomial in \(nt\) and thus in \(t\). It follows that \(\mathcal{O}_N = q_n(\mathbb{R}) = q_n(\mathbb{R}) = q_n(\mathbb{C})\) which we know how to compute.

Next we consider the class of \textit{switching systems}, that is, hybrid systems in which every pair of locations is connected by an edge and in which variables are no updated on discrete edges. It is known that reachability is undecidable even for this restricted class [6] of systems.

However, as we show below, building on Proposition 4 one can compute computing strongest algebraic invariants in this setting.

\textbf{Procedure} Semigroup-Closure\((A_1, \ldots, A_k)\)

\begin{verbatim}
input : \(A_1, \ldots, A_k \in \mathbb{A}^{d \times d}\)

1. \(H := \{I_d\}\)
2. \(G_1 := \{e^{A_1 t} : t \geq 0\}\), \(\ldots, G_k := \{e^{A_k t} : t \geq 0\}\)

3. repeat
   4. \(H_{old} := H\)
   5. for \(i \in \{1, \ldots, k\}\) do
      6. \(H := H \cdot G_i\)
   7. until \(H_{old} = H\)

output : \(H\)
\end{verbatim}

\textbf{Proposition 5.} Algorithm \texttt{Semigroup-Closure} (shown below) terminates and outputs the Zariski closure of the sub-semigroup of \(\text{GL}_d(\mathbb{C})\) generated by \(\{e^{A_1 t}, \ldots, e^{A_k t} : t \geq 0\}\).
Proof. First note that the effectiveness of Line 2 relies on Proposition 3.

Now we argue that \( H \) in the algorithm is always an irreducible variety. For this it suffices to show that if \( X \subseteq \text{GL}_d(\mathbb{C}) \) is an irreducible variety then so is \( Y := X \cdot \{ e^{At} : t \geq 0 \} \) for any matrix \( A \in \mathbb{C}^{d \times d} \). First observe that if \( X \) and \( Z \) are irreducible sets then so is \( X \cdot Z \), thus is it enough to show that \( G \equiv \overline{S} \) is irreducible, where \( S = \{ e^{At} : t \geq 0 \} \). But \( S \) is a semigroup, thus \( G \) is a group. This makes \( G \) a linear algebraic group, which is therefore irreducible if and only if it is (Zariski-)connected. But \( G \) being the closure of \( S \) means it is enough to show that \( S \) is Zariski-connected, and hence enough to show that it is Euclidean-connected. The latter is trivial since every element of \( S \) is path-connected to \( I_d \).

Now a strictly increasing chain \( H_1 \subseteq H_2 \subseteq \cdots \) of irreducible sub-varieties of \( \text{GL}_d(\mathbb{C}) \) has length at most the dimension of \( \text{GL}_d(\mathbb{C}) \), which is \( d^2 \). Thus Algorithm Semigroup-Closure terminates after at most \( d^2 \) iterations of the outer loop. It is clear that the terminating value of the algorithm is the Zariski closure of the sub-semigroup of \( \text{GL}_d(\mathbb{C}) \) generated by \( \{ e^{At_1}, \ldots, e^{At_m} : t \geq 0 \} \).

Now consider a switching system \( A = (Q, A, E, T) \). Let \( G \) be the Zariski closure of the semigroup generated by the matrices \( e^{At} \), for \( q \in Q \) and \( t \geq 0 \), which can be computed by Proposition 5. Then \( V(A) = \{ V_q : q \in Q \} \), the real Zariski closure of the collecting semantics of \( A \), is such that \( V_q = G \cdot X \cap \text{GL}_d(\mathbb{R}) \) for every \( q \in Q \), where \( X = \bigcup_{q \in Q} T_q \). But then \( V(A) \) is computable from \( G \) and \( T \).

Theorem 6. Given a switching system \( A \), one can compute \( V(A) \).

6 Reducing Continuous Dynamics to Constructible Discrete Dynamics

Lemma 7. Let \( A \) be an automaton, then \( V(A) \) is the least fixpoint of the map \( X \mapsto \Phi_A(X) \).

Proof. Let \( S \) denotes the collecting semantics of \( A \), then

\[
\begin{align*}
V(A) &= \overline{S} \\
&= \Phi_A(\overline{S}) \\
&= \Phi_A(S) \\
&= \Phi_A(V(A))
\end{align*}
\]

thus \( V(A) \) is indeed a fixed-point. Conversely, let \( X \) be such that \( X = \overline{\Phi_A(X)} \). Then \( X \) is closed and clearly \( \Phi_A(X) \subseteq \overline{\Phi_A(X)} = X \) so it is a pre-fixpoint of \( \Phi_A \). By virtue of \( S \) being the least (pre-)fixpoint of \( \Phi_A \) we must have \( S \subseteq X \). But then \( \overline{S} \subseteq X \) i.e., \( V(A) \subseteq X \).

Proposition 8. Given a linear hybrid automaton \( A \), one can compute a constructible affine program \( A' \) that has the same algebraic invariants, i.e., \( V(A) = V(A') \).

Proof. The idea is to replace each continuous dynamics \( x' = Ax \) by a closed (and thus constructible) set of discrete transitions: \( \{ e^{At} : t \in \mathbb{R}_{\geq 0} \} \), which we know how to compute thanks to Proposition 3. Graphically:
Formally, let $A = (Q, A, E, T)$ be a linear hybrid automaton. Define the constructible affine program $A' = (Q, A', E', T)$ where $A'_q = 0$ for all $q \in Q$ and

$$E' = E \cup \{ (q, X, q) : q \in Q, X \in \overline{O_A} \}$$

where $O_A := \{ e^{At} : t \in \mathbb{R}_{\geq 0} \}$. Note that it is constructible because $\overline{O_A}$ is closed (and thus constructible). We will now relate $\Phi_A$ and $\Phi_{A'}$: let $X \in \mathcal{P}(\mathbb{C}^{d})^{Q}$ and observe that

$$\Phi_A(X)_q = T_q \cup (O_A \cdot X)_q \cup \bigcup_{(p, B, q) \in E} BX_q$$

$$\subseteq T_q \cup (\overline{O_A} \cdot X)_q \cup \bigcup_{(p, B, q) \in E} BX_q$$

$$= \Phi_{A'}(X)_q.$$ 

Let $S^A$ (resp. $S^{A'}$) denote the collecting semantics of $A$ (resp. $A'$), that is $S^A$ is the least fixpoint of $\Phi_A$. It follows that

$$\Phi_A(S^A) \subseteq \Phi_A(\Phi_{A'}(X)) = S^{A'},$$

i.e., $S^{A'}$ is a pre-fixpoint of $\Phi_A$ and thus it must be the case that $S^A \subseteq S^{A'}$. It immediately follows that $V(A) \subseteq V(A')$. Conversely, we also have that

$$\Phi_{A'}(S^A)_q = T_q \cup (O_A \cdot S^A)_q \cup \bigcup_{(p, B, q) \in E} BS_q$$

$$= T_q \cup (\overline{O_A} \cdot S^A)_q \cup \bigcup_{(p, B, q) \in E} BS_q$$

$$= T_q \cup (\overline{O_A} \cdot S^A)_q \cup \bigcup_{(p, B, q) \in E} BS_q$$

$$= \Phi_{A'}(S^A)_q$$

and similarly for $A'$. It follows that

$$V(A)_q = \Phi_A(S^A)_q = \Phi_A(\Phi_{A'}(X))_q = \Phi_{A'}(V(A)_q).$$

Thus $V(A)$ is a fixpoint of $X \mapsto \Phi_{A'}(X)$. But $V(A')$ is the least fixpoint of this map by Lemma 7 and thus $V(A') \subseteq V(A)$. \hfill ▷

7 Reducing Continuous Dynamics to Finite Discrete Dynamics

In the previous section, we saw that given a linear hybrid automaton one can compute a constructible affine program with the same set of algebraic invariants. In this section we show how to compute a finite affine program with the same set of algebraic invariants. The idea is to replace the continuous evolution of the variables in each location of a hybrid automaton with a finite set of discrete transitions. Graphically this corresponds to rewriting the automaton as follows:
Mathematically, the task is as follows: Given $A \in \mathbb{K}^{d \times d}$, find $B_1, \ldots, B_k \in \mathbb{K}^{d \times d}$ such that $\{e^{At} : t \in \mathbb{R}\} = \{B_1, \ldots, B_k\}$. There is a conceptually simple approach to this problem: namely for every matrix $A \in \mathbb{K}^{d \times d}$ and rational number $\tau$ we have $\{e^{At} : t \in \mathbb{R}\} = \{e^{At}\}$ (see Section A). But this does not fulfill our desiderata, since it is not possible in general to find $\tau \in \mathbb{R}$ such that $e^{At}$ has exclusively algebraic entries. Nevertheless given $A \in \mathbb{K}^{d \times d}$ it is possible to find $B \in \mathbb{K}^{d \times d}$ such that $\{e^{At} : t \in \mathbb{R}\} = \{B\}$. The idea is to construct $B$ such that there is a correspondence between the set of additive relations satisfied by the eigenvalues of $A$ and the multiplicative relations satisfied by the eigenvalues of $B$.

**Proposition 9.** Let $a_1, \ldots, a_d \in \mathbb{C}$ be algebraic numbers. Then we can compute rational numbers $\lambda_1, \ldots, \lambda_d$ such that $a_1n_1 + \cdots + a_dn_d = 0$ iff $\lambda_1^{n_1} \cdots \lambda_d^{n_d} = 1$ for all $n_1, \ldots, n_d \in \mathbb{Z}$.

**Proof.** Let $s$ be the dimension of the $\mathbb{Q}$-vector space spanned by $a_1, \ldots, a_d$. By computing a basis over $\mathbb{Q}$ for the number field $\mathbb{Q}(a_1, \ldots, a_d)$ and the respective rational coordinates of $a_1, \ldots, a_d$ with respect to this basis, we obtain an $s \times d$ integer matrix $A$ such that for every integer vector $x = (n_1, \ldots, n_d) \in \mathbb{Z}^d$ we have $n_1a_1 + \cdots + n_da_d = 0$ iff $Ax = 0$.

Now write $A = PBQ$, where $B$ is an $s \times d$ matrix in Smith normal form and $P, Q$ are unimodular square matrices. Since $B$ has rank $s$ it has the form $B = (D \ 0)$ for $D$ an $s \times s$ diagonal matrix of full rank.

We define positive integers $\mu_1, \ldots, \mu_d$ as follows. Choose $\mu_1, \ldots, \mu_s$ to be the first $s$ prime numbers and let $\mu_{s+1} = \cdots = \mu_d = 1$. Write $Q = (q_{ij})$ and define $\lambda_i = \mu_1^{q_{ij}} \cdots \mu_d^{q_{ij}}$ for $i \in \{1, \ldots, d\}$.

Then for all $n_1, \ldots, n_d \in \mathbb{Z}$ we have

$$\lambda_1^{n_1} \cdots \lambda_d^{n_d} = 1 \iff \mu_1^{q_{11}} \cdots \mu_d^{q_{d1}} = 1$$

$$\iff (Qx)_1 = 0, \ldots, (Qx)_s = 0$$

$$\iff BQx = 0 \quad \text{(since } B = (D \ 0))$$

$$\iff PBQx = 0 \quad \text{(since } P \text{ is invertible)}$$

$$\iff Ax = 0$$

$$\iff a_1n_1 + \cdots + a_dn_d = 0.$$  

**Corollary 10.** Let $D$ be a $d \times d$ diagonal matrix with algebraic entries. Then there exists a diagonal matrix $D'$, of the same dimension and with rational entries, such that $\{e^{Dt}\} = \{D'\}$.

**Proof.** Write $D = \text{diag}(a_1, \ldots, a_d)$ and let rational numbers $\lambda_1, \ldots, \lambda_d$ be chosen as in Proposition 9, i.e., such that $a_1n_1 + \cdots + a dn_d = 0$ iff $\lambda_1^{n_1} \cdots \lambda_d^{n_d} = 1$ for all $n_1, \ldots, n_d \in \mathbb{Z}$. Define $D' = \text{diag}(\lambda_1, \ldots, \lambda_d)$. By Lemma 3 the ideal of the variety $\langle e^{Dt} \rangle$ is generated by $z^n - z^m$ such that $(n_1 - m_1)a_1 + \cdots + (n_d - m_d)a_d = 0$. On the other hand, it follows from Lemma 6 that the ideal of the variety $\langle D' \rangle$ is generated by $z^n - z^m$ such that $\lambda_1^{n_1 - m_1} \cdots \lambda_d^{n_d - m_d} = 1$. But by construction the additive relations of $a$ are the same as the multiplicative relations of $\lambda$, therefore the ideals are the same. It follows $\langle e^{Dt} \rangle = \langle D' \rangle$.

**Proposition 11.** Let $A \in \mathbb{Q}^{d \times d}$ be a rational matrix. Then there exists an algebraic matrix $B$ such that $\{e^{At}\} = \{e^{At} : t \in \mathbb{R}\}$.

**Proof.** Let $P$ be an invertible matrix such that $A = P^{-1}(D+N)P$ with $D = \text{diag}(a_1, \ldots, a_d)$ diagonal and $N$ a nilpotent Jordan matrix. By Corollary 10 there exists a rational diagonal matrix $D'$ such that $\{D'\} = \{D\}$. We now define $B := P^{-1}(D'e^N)P$ where
\[ D' = \text{diag}(\lambda_1, \ldots, \lambda_d). \] Note that \( e^N \) is a matrix of rational numbers. Then we have:
\[
\langle e^A \rangle = P^{-1}(e^D e^N) P = P^{-1}(e^D) \cdot \langle e^N \rangle P = P^{-1}(D^t) \cdot \langle e^N \rangle P = P^{-1}(D' e^N) P = \langle B \rangle.
\]

**Proposition 12.** Given a linear hybrid automaton \( \mathcal{A} \), one can compute a finite affine program \( \mathcal{A}' \) that the same algebraic invariants, i.e., \( V(\mathcal{A}) = V(\mathcal{A}') \).

**Proof.** Suppose that \( \mathcal{A} = (Q, A, E, T) \). We define \( \mathcal{A}' = (Q, A', E', T) \), where 
\[
A'_q = 0 \quad \text{for all } q \in Q \quad \text{and}
\]
\[
E' = E \cup \{(q, B_q, q) : q \in Q\},
\]

with \( B_q \) is an algebraic matrix such that \( \langle e^{A_q} \rangle = \langle B_q \rangle \) for all \( q \in Q \). The existence of the matrices \( B_q \) is guaranteed by Proposition 11. In other words, we obtain \( \mathcal{A}' \) from \( \mathcal{A} \) by setting the derivative of all variables to 0 in every location and by adding a compensatory self-loop edge to every location.

The reasoning that \( V(\mathcal{A}) = V(\mathcal{A}') \) is entirely analogous to that in the proof of Proposition 8.

### 8 Switching Systems with Guards

In this section we consider linear hybrid automata with no discrete updates on the variables but with equality guards on the discrete mode changes. For such systems there is a smallest algebraic inductive invariant, which can be obtained as the (location-wise) intersection of the family of all algebraic inductive invariants. However, as we show in this section, this invariant is no longer computable. In other words, in the presence of equality guards the analog of Theorem 2 fails. (As an aside we remark that the discrete mode changes no longer induce Zariski continuous maps on configurations if there are equality guards. Hence we cannot necessarily recover the smallest algebraic inductive invariant as the Zariski closure of the collecting semantics).

**Theorem 13.** There is no algorithm that computes the strongest algebraic inductive invariant for the class of switching systems with equality guards.

**Proof Sketch** (see full proof in appendix). The idea is to simulate a 2-counter machine in such a way that if the machine has an infinite run then the strongest invariant has dimension 2, and otherwise it has dimension 1. Since the dimension of an algebraic set can be effectively determined; this concludes the sketch.

A Time Discretisation

Proposition 14. For a rational matrix $A \in \mathbb{Q}^{d \times d}$ we have
\[
\{e^{At} : t \in \mathbb{R}\} = \overline{\{e^A\}}.
\]

Proof. Suppose that $A$ is diagonalisable—say $A = U^{-1}DU$ for some invertible matrix $U$ and $D = \text{diag}(a_1, \ldots, a_d)$. It suffices to prove that $\{e^{Dt} : t \in \mathbb{R}\} = \overline{\{e^D\}}$.

Consider a multiplicative relationship among the eigenvalues of $e^D$—say $(e^{a_1})^{n_1} \cdots (e^{a_d})^{n_d} = 1$, where $n_1, \ldots, n_d \in \mathbb{Z}$. Then $a_1n_1 + \cdots + a_dn_d \in (2\pi i)\mathbb{Z}$. But since $a_1, \ldots, a_d$ are algebraic numbers, we must in fact have $a_1n_1 + \cdots + a_dn_d = 0$. It follows that $a_1n_1 + \cdots + a_dn_d = 0$ for all $t \in \mathbb{R}$ and hence $(e^{a_1t})^{n_1} \cdots (e^{a_dt})^{n_d} = 1$ for all $t \in \mathbb{R}$, i.e., the same multiplicative relation also holds among the eigenvalues of $e^{Dt}$.

Since the ideal of all polynomial relations satisfied by $\{e^D\}$ is generated by the multiplicative relations satisfied by the eigenvalues of $e^D$, we have that for any $t \in \mathbb{R}$, matrix $e^{Dt}$ satisfies all polynomial relations satisfied by $\{e^D\}$. This proves the proposition in case $A$ is diagonalisable.

Next, suppose that $A$ is nilpotent. The fact that $\{e^{At} : t \in \mathbb{R}\} = \overline{\{e^A\}}$ is already shown in Section 3.3 of Derksen, Jeandel, and Koiran.

The general case can be handled by reduction to the diagonalisable and nilpotent cases as in Proposition 14.

Proposition 14 crucially relies on the fact that $\pi$ does not appear in the description of $A$. Indeed, consider the case that $A = (2\pi i)I \in \mathbb{C}^{1 \times 1}$. Then $\{e^{At} : t \in \mathbb{R}\} = \{z \in \mathbb{C} : |z| = 1\}$ is the unit circle. However $\{e^{At} : n \in \mathbb{Z}\} = \{1\}$ is a singleton. Such an example is possible because the map $z \in \mathbb{C} \mapsto e^{Az}$ is not Zariski-continuous in general.

B Proof of Theorem 13

Recall that a non-deterministic 2-counter machine $M$ consists of two counters $C$ and $D$ and a list of $n$ instructions. Each instruction increments one of the counters, decrements one of the counters, or tests one of the counters for zero. After executing a counter update or a successful test, the machine proceeds nondeterministically to one of two specified instructions. The machine halts if it executes a test instruction whose condition is false. Given an instruction
i, if j is one of the two possible successors of i then we call the pair (i, j) a transition of M. Initially M starts with both counters zero and instruction 1 is the first to be executed. A configuration of M is a triple consisting of the current instruction and the current counter values. The problem of whether such a machine M can reach infinitely many configurations from its initial configuration is undecidable.

Corresponding to such a 2-counter machine M we define a linear hybrid automaton $A = (Q, A, E, q_0)$ in dimension 3. We think of $A$ as having continuous variables $c, d, t,$ where $c$ and $d$ respectively correspond to the counters of $M$. Each variable has constant derivative in each location, which is zero unless otherwise specified. For each instruction $i$ of $M$ we postulate a location $q_i$ of $A$ and for each transition $(i, j)$ of $M$ we postulate a location $q_{i,j}$ of $A$. Variable $t$ has slope 1 in each location $q_i$ and slope $-1$ in each location $q_{i,j}$. For every transition $(i, j)$ of $M$, automaton $A$ has an edge from $q_i$ to $q_{i,j}$ with guard $t = 1$ and an edge from $q_{i,j}$ to $q_j$ with guard $t = 0$. Intuitively, if an execution of $A$ correctly simulates a run of $M$ then $A$ spends one time unit in each location, alternating between locations $q_i$ that correspond to instructions of $M$ and locations $q_{i,j}$ that correspond to transitions of $M$.

Suppose that the $i$-th instruction of $M$ performs an incrementation $C := C + 1$. Then variable $C$ has slope 1 in location $q_i$. Likewise if the $i$-th instruction if $C := C - 1$, then variable $c$ has slope $-1$ in location $q_i$. If the $i$-th instruction of $M$ is the zero test $C = 0$, then the edge from location $q_i$ to $q_{i,j}$ in $A$ has guard $c = 0$. There are corresponding constructions for counter operations and tests on counter $D$.

This completes the description of $A$. We now claim that:

1. If $M$ can only reach finitely many configurations from the initial configuration then $V(A) = \{V_q : q \in Q\}$, the Zariski closure of the collecting semantics, is an inductive invariant that has dimension one.

2. If infinitely many configuration are reachable from the initial configuration of $M$ then the smallest inductive invariant has dimension strictly greater than one.

To prove the claim, note that for each reachable configuration $(i, z_1, z_2)$ of $M$, the collecting semantics $\Phi(A)_{q_i}$ contains a half-line $L$ containing the point $(z_1, z_2, 0)$, whose direction is determined by the slopes of the respective variables of $A$ in location $q_i$. The Zariski closure of $L$ is the affine hull of $L$, i.e., the corresponding full line containing $L$. Crucially, the points added to $L$ to obtain the full line are all predecessors of $L$ under the flow relation of $A$. In particular the Zariski closure is inductive: it remains closed under the transition relation of $A$. In particular, if $M$ can only reach finitely many configurations, then the Zariski closure of the collecting semantics consists of finitely many lines in each location (and so has dimension one) and is moreover an inductive invariant.

Suppose $M$ can reach infinitely many configurations. Since any algebraic inductive invariant must in particular contain the Zariski closure of the collecting semantics, it follow that any algebraic inductive invariant must contain infinitely many lines in some location and thus must have dimension strictly greater than one.

Since the dimension of an algebraic set can be effectively determined, we conclude that it is not possible to compute the smallest algebraic invariant of a linear hybrid automaton with equality guards (even with a no discrete updates of the variables).
