The PRI Apple Breeding Program

Jules Janick

Department of Horticulture and Landscape Architecture, Purdue University, West Lafayette, IN 47907-1165

ORIGINS

The PRI cooperative scab-resistant apple breeding program between Purdue University, Rutgers, The State University of New Jersey, and the University of Illinois has a long and interesting history involving many scientists and collaborators (D.F. Dayton, “A history of the Illinois–Indiana–New Jersey cooperative apple breeding program,” unpublished; Crosby et al., 1992; Janick, 2002). The original program dates to a formal 1945 collaboration between J. Ralph Shay (1918–1980), pathologist at Purdue University, and L. Fredric Hough (1915–1993), horticulturist at the University of Illinois, to develop scab-resistant apples. Shay was a man of vision who was enthusiastic about his work and about science in general. He had an outgoing personality, made friends easily, and had the ability to stimulate enthusiasm in others. Hough was an extraordinary fruit breeder, full of optimism, whose credo of “one more generation” typified his philosophy of fruit breeding, which was to cherish diversity, pollinate with abandon, and extravagantly share seedlings with everyone. Pollination was his happiest time as he, with carloads of students, pursued Spring in her northward trek in an attempt to improve the odds for favorable recombinants—always just a generation away. Interestingly, the PRI program was initiated before the environmental implications of pesticides were realized, and the goal was simply one of serving the needs of fruit growers.

The germplasm exploited by Shay and Hough can be traced to breeding studies of C.S. Crandall (1852–1929) at the University of Illinois carried out as early as 1907. Crandall had assembled a large collection of Malus species and forms at the beginning of the century and initiated an intensive study of crosses between cultivated apples and crab-like forms. A summary of Crandall’s work, published in University of Illinois Bulletin 275 (Crandall, 1926), describes all the material in the program. Crandall, influenced by the rediscovery of Mendel, was attempting to determine inheritance patterns in Malus. Ironically, he did not work with characteristics that would enable him to identify single genes or evaluate his material for disease resistance. The voluminous data he collected and maintained at the University of Illinois has never been completely analyzed, although the designations reported in Bulletin 275 describing his species sources have become justly famous. The selection he labeled Malus floribunda 821 was the original source of the Vf gene. Fortunately, his breeding material was maintained following his retirement in 1927, but remained unevaluated until L.F. Hough joined the department in 1942 as a graduate student and plant-breeding assistant.

Spring 1943 was unusually cool and wet, resulting in a severe epidemic of scab that defoliated all susceptible unsprayed apples trees. Hough noted that one progeny, an F1, of M. floribunda 821 × Rome Beauty, segregated at a ratio of 1 resistant : 1 susceptible, suggesting the involvement of a single gene, later termed Vf. Hough published his results with the Proceedings of the American Society of Horticultural Science in his famous paper “A Survey of the Scab Resistance of the Foliage of Seedlings in Selected Apple Progenies” (Hough, 1944). The paper was brought to the attention of J.R. Shay, a young professor who joined the Purdue’s Department of Botany and Plant Pathology from Arkansas and who had received his PhD from the University of Wisconsin where a program on the pathogenicity of Venturia inaequalis had been under investigation. (In the 1940s, considerable interest in the genetics of the ascomycetes had been engendered by the work of Beadle and Tatum in Neurospora.) Shay and Hough decided to collaborate on a scab-resistance breeding program with the objective to advance genetic resistance identified by Hough into improved horticultural backgrounds and identification of additional resistant Malus germplasm through testing of material in arboreta and other collections. The first screened hybrid progenies were planted in the field in 1947 and began fruiting at Illinois in 1951. A formal cooperative program was established in 1945 between the agricultural experiment stations associated with Purdue University and the University of Illinois.

THE TEAM

In 1948, Hough moved to the Department of Horticulture and Forestry at Rutgers, The State University of New Jersey, and, shortly thereafter, Rutgers joined Illinois and Purdue as the third partner in the collaboration, thereby making available to the program a large volume of valuable susceptible apple germplasm developed by the late M.A. Blake. In 1950, Daniel F. Dayton joined the program at Illinois while pursuing graduate studies. Dan was a witty, energetic New Englander from New Hampshire who was equally at home in the orchard as improvising on the organ. Edwin B. Williams, a graduate student of Shay’s in plant pathology, a native Hoosier, and a World War II veteran who had served in the Philippines, became a skilled pomologist to complement his abilities as a pathologist, fisherman, and poker player. Dayton and Williams remained with the program upon completion of their PhD degrees (Fig. 1). Dayton continued leadership for the Illinois

The original breeding program was uniquely a true cooperative effort between the three stations. While crossing was carried out at each location, the bulk of the successful hybridizations were achieved by Hough, who each spring traveled with his team of pollinators from New Brunswick, N.J., to Geneva, N.Y., and on to New Hampshire, following spring in its northern trek. All seeds were assembled at Purdue University and screened for scab at the Department of Botany and Plant Pathology. Resistant seedlings were either planted directly to the field or grown in a nursery and then divided between cooperators, with the bulk of the progenies evaluated in Indiana and Illinois. Fruit of promising seedlings each year were compared in a joint display and used in crosses in the following years. By 1967 the most promising selections, called co-ops to underscore the cooperative nature of the program, were released to interested testers including fruit growers and experiment stations in other states. In addition, promising selections were shared worldwide with international cooperators.

ACCOMPLISHMENTS

Up to the present time, more than 1500 selections have been made of which 44 have been released for advanced testing as co-ops, and, of these, 16 have been named as shown in Table 3. Joint releases from other PRI selections include ‘McShay’ (1988), released in cooperation with Oregon State University; ‘Priam’ (1974) and ‘Juliet’ (1999), released in France; ‘Primiera’ (1995), released in Italy; ‘Primiviera’ (1996), released in Quebec, Canada; and ‘Constance’ (1995), released in Germany by an organic grower. ‘Nambu’ (1994) is a PRI selection that was released in England under the assistance of the late A.G. Brown of the John Innes Institute.

without authorization in Japan. ‘Viking’ (1969), released in Wisconsin, is a PRI selection but proved to be scab-susceptible.

An attempt was made to carry each source of resistance forward, but resistance derived from *M. floribunda* received the most attention because two F₂ selections of the original *M. floribunda* 821 × Beauty cross carrying the designation F₂ 26829 and F₂ 28830 were more advanced in size and quality. Selection F₂ 26829, while only two generations from the original small-fruited species, had unusually good quality and was about 5 cm in diameter. A breakdown of the pedigrees of the 44 co-op selections indicates that all of the 44 released date back to *M. floribunda*, although Co-op 41 also has *M. atrosanguinea* 804 in its pedigree. Of the 43 floribunda selections, only one co-op derived from 26830 entirely (Co-op 11), one has both F₂ 26829 and F₂ 26830 in its pedigree, and three have F₂ 26829 on both sides. The scab-resistance program at Cornell University originated from material derived from F₂ 26829 and the two releases ‘Liberty’ and ‘Freedom’ carry the *Vf₁* gene.

In 1963, the three cooperating universities, in conjunction with other interested American and Canadian breeders, formed a loose cooperative organization known as The Apple Breeder Cooperative (ABC), and workers in several other states have participated in testing selections. Introductions of the co-op selections and the release of scab-immune cultivars created great interest in the program throughout the world. Several countries, including Australia, Brazil, Canada, Czechoslovakia, England, France, Italy, Poland, South Africa, Romania, Sweden, and Russia, have incorporated PRI germplasm in their apple-breeding programs. By 2000, more than 50 scab resistant selections had been released.

**FUTURE PROSPECTS**

The excellent progress in developing new apple scab-immune cultivars was due to administrative support at the three institutions, the ability and willingness of the cooperating workers to pool their efforts and facilities, and the tremendous effort carried out in the Purdue University Department of Botany and Plant Pathology, under the guidance first of J.R. Shay and later of E.B. Williams, to carry out an efficient greenhouse screening procedure. About 380,000 seedlings were screened. Although the scab-resistance program still exists between the three institutions, activity has declined as the universities at each location reduced support. By 1993 the Department of Botany and Plant Pathology discontinued its input and I carried on the Purdue program, being directed to be concerned only with evaluating the remaining selections, although crossing continued. At the University of Illinois, Korban’s program became oriented to the molecular biology of scab resistance. Screening has continued at Rutgers, but the apple-breeding program is just one small part of a general fruit-breeding program. However, just as the universities were fatigued with funding, a number of fruit growers became believers in the program. Several serendipitous discoveries were made. By impatiently using the first fruiting selections from crosses as parents, reduced juvenility and increased precocity were selected. The advantages of diversity were demonstrated by the incorporation of a tolerance to a number of insects and diseases and long storage ability. The impact of the program is expected to be fully realized in the 21st century, as more breeding programs worldwide incorporate this disease resistant material developed by the PRI program.

**CONCLUSIONS**

The PRI program remains as an example of what can be accomplished in tree-fruit-breeding programs, long discounted for their slow progress, by a concerted attempt at transferring desirable genes from interspecific hybridization. Several serendipitous discoveries were made. By impatiently using the first fruiting selections from crosses as parents, reduced juvenility and increased precocity were selected. The advantages of diversity were demonstrated by the incorporation of a tolerance to a number of insects and diseases and long storage ability. The impact of the program is expected to be fully realized in the 21st century, as more breeding programs worldwide incorporate this disease resistant material developed by the PRI program.
