Prospects for p-wave paired BCS states of fermionic atoms

L. You and M. Marinescu
School of Physics, Georgia Institute of Technology, Atlanta, GA 30332-0430

We present theoretical prospects for creating p-wave paired BCS states of magnetic trapped fermionic atoms. Based on our earlier proposal of using dc electric fields to control both the strength and anisotropic characteristic of atom-atom interaction and our recently completed multi-channel atomic collision calculations we discover that p-wave pairing with $^{40}$K and $^{82,84,86}$Rb in the low field seeking maximum spin polarized state represent excellent choices for achieving superfluid BCS states; and may be realizable with current technology in laser cooling, magnetic trapping, and evaporative/sympathetic cooling, provided the required strong electric field can be applied. We also comment on the prospects of similar p-wave paired BCS states in $^6$Li, and more generally on creating other types exotic BCS states. Our study will open a new area in the vigorous pursuit to create a quantum degenerate fermionic atom vapor.

The success of atomic Bose-Einstein condensation (BEC) [1] has induced an exponential growth of interest in the properties of ultracold dilute quantum gases. Of particular interest now is the physics of trapping and cooling of fermionic atoms [2]. Indeed the prospect of superfluidity with dilute atomic vapors has already been studied by several groups [3-6].

In this Letter we present a theoretical study of the prospect of superfluidity in magnetic trapped fermionic atoms. We conduct our discussions for the three alkali species currently being investigated at several labs: $^6$Li ($I = 1$), $^{40}$K ($I = 4$), and $^{82,84,86}$Rb ($I = 1, 2, 2$) [7]. This Letter is organized as follows: We briefly review the existing proposals for BCS states of magnetically trapped atoms [3-5], after which we present our proposal based on the use of external dc-electric (dc-E) fields to induce anisotropic atom-atom interactions [8]. We then address its advantages and present results of our detailed multi-channel atomic collision calculations. We conclude with a discussion of other possibilities of BCS states offered by our proposal, notably, the analogies of the Anderson-Brinkman-Morel [9] and Balian-Werthamer [10] states in $^3$He [11].

In the standard BCS theory [13] of superconductivity the attractive interaction between electrons of opposite spin and momentum causes the (Cooper) instability of the filled Fermi sea ground state. Physically, this effect can be roughly understood as some kind of condensation of “bosonic” Cooper pairs [2][13]. In the weak coupling limit when $k_B T_c \ll \hbar \omega_D$, ($\hbar \omega_D$ is a characteristic energy over which an attractive interaction persists around the Fermi surface), the transition temperature $T_c$ is

$$k_B T_c \sim \hbar \omega_D \exp \left( -\frac{1}{N(0)|V|} \right).$$

(1)

$N(0)$ is the electronic density of states at the Fermi surface, and is $\propto k_F$, the Fermi momentum. $V$ is the two body scattering amplitude, assumed constant and negative around the Fermi surface. Although derived for the
case of a homogeneous system, as argued in several recent studies [3,6] Eq. (1) should also provide good estimates for current magnetic traps where the local density approximation is expected to be valid. We note that the computation of $V$ is a complicated and difficult many-body problem, and reliable values can rarely be obtained. For an ultracold weakly interacting dilute atom gas, the situation is quite different, the scattering amplitude can be accurately computed, and is usually dominated by the lowest several partial waves (at sub-mini-Kelvin temperatures). The effective interaction $V_l$ for the dominant $l$-th partial wave term is $\sim \delta_l(k_F)/k_F$, where $\delta_l(k_F)$ is the phase shift for the $l$-th partial wave.

In the pairing of two fermions the Pauli exclusion principle requires the total wavefunction to be antisymmetric. Therefore the orbital angular momentum $l$ has to be odd for spin symmetric pairs, and even for spin asymmetric ones. For spherically symmetric interatomic potentials which vanish exponentially, $\delta_l(k) \sim k^{2l+1}$ at low energies when $k \to 0$. For a potential of the asymptotic form $-1/R^n$ ($n > 4$), the phase shift scales as $\delta_l(k) \sim k^{2l+1}$ for $l < (n-3)/2$ and as $\delta_l(k) \sim k^{n-2}$ for $l > (n-3)/2$.

At a large internuclear distance $R$, the typical ground state interatomic potential is asymptotically dominated by the van der Waals term $-C_6/R^6$, where $C_6$ is the dispersion coefficient. Therefore the phase shift scales as $\delta_l(k) \sim k^{2l+1}$ for $l = 0, 1$ and as $\delta_l(k) \sim k^4$ for $l \geq 2$. The only significant term is then from the s-wave, described by the scattering length $s_{sc} \equiv -\lim_{k \to 0} \delta_0(k)/k$.

Based on the observation above, one realizes that atoms in spin symmetric states interact only through a vanishingly small p-wave ($\sim k^3$). For $^6$Li in the triplet (electronic spin symmetric) state, the p-wave scattering length defined as $a_{sc-p}^3 \equiv \lim_{k \to 0} -\delta_0(k)/k^3$ [14], is about $-35$ (a.u.), corresponds to a very weak attraction. While the s-wave triplet scattering length $a_{sc}$ is enormous at about $\sim -21600$ (a.u.) due to a shallow bound state [13].

In a recent paper Stoof et al. studied the prospects for superfluidity of magnetically trapped $^6$Li [3]. In the maximum polarized state [6], a p-wave BCS pairing occurs at a transition temperature of

$$T_c \sim \frac{\epsilon_F}{k_B} \exp \left[ \frac{\pi}{2(k_F|a_{sc-p}|)^3} \right], \quad (2)$$

too slow to be practical. For instance, with a density of $10^{12}/\text{cm}^3$, we have $\epsilon_F/k_B \sim 600$ (nK) and $k_F|a_{sc-p}| \sim 7 \times 10^{-3}$ [3].

Kagan et al. suggested the trapping of atoms in multiple hyperfine states [3]. They discovered that two atoms in the same state ($|6\rangle$) of $^6$Li can attract through phonon induced interactions (caused by density fluctuations in the other state, $|5\rangle$ of $^6$Li), and pairing occurs at

$$T_c \sim \frac{\epsilon_F}{k_B} \exp \left[ -13 \left( \frac{\pi}{2k_F|a_{sc}|} \right)^2 \right], \quad (3)$$

where the large s-wave scattering length (for $^6$Li) enters. Despite a dramatic enhancement (from the $k_F$ depen-
dence), this scheme is still difficult to realize. For a density of about $10^{12} \text{cm}^{-3}$ per state, (a total density of $2 \times 10^{12} \text{cm}^{-3}$), one gets $k_F|a_{sc}| \sim 0.4$. The prefactor $13$ in the exponent dictates an excessively low temperature.

Recently Stoof et. al. [3] proposed an s-wave pairing of atoms in different hyperfine states ($|5\rangle$ and $|6\rangle$ of $^6\text{Li}$) which occurs at

$$T_c \sim \frac{\epsilon_F}{k_B} \exp \left( -\frac{\pi}{2k_F|a_{sc}|} \right).$$

(4)

For a density of $\sim 10^{12} \text{cm}^{-3}$, $T_c$ is about a few tens of a nano Kelvin, potentially within experimental reach if the atomic decay channels are suppressed [16]. There are, however, major obstacles towards trapping more than one hyperfine state simultaneously: first, the two body exchange loss channel is now open and the dipolar rates generally also increase; second, for stable BCS states, the pairing energies for atoms in different hyperfine states have to overcome the Zeeman energy deficit. An interesting proposal was also recently suggested by Modawi et. al. [4] utilizing the s-wave pairing of atoms in spin anti-symmetric states with a result similar to Eq. (4).

In a recent letter [8] we proposed to control atom-atom interactions at ultra-low temperatures with a dc-E. In the presence of a dc-E the spherical symmetry of the interacting atoms is distorted, consequently the long-range inter-atomic potential is modified by the addition of an anisotropic dipole interaction term

$$V_E(R) = -\frac{C_E}{R^3} P_2(\cos \theta),$$

(5)

where $C_E = 2\epsilon^2 \alpha_1^A(0)\alpha_1^B(0)$, $\epsilon$ is the strength of the dc-E and $\alpha_1^A,B(0)$ are the static atomic dipole polarizabilities for the two atoms denoted by $A$ and $B$. $P_2$ is the Legendre polynomial of order 2 and $\theta$ is the angle between the directions of the electric field and the internuclear axis. A complete low energy scattering treatment reveals that the total two body (unsymmetrized) scattering amplitude takes the form [8]

$$f(\vec{k}, \vec{k}') = 4\pi \sum_{lm,l'm'} t_{lm,m'}^l(k)Y_{lm}^*(\hat{k})Y_{l'm'}(\hat{k}').$$

(6)

The reduced T-matrix elements $t_{lm,m'}^l \equiv \lim_{k \to 0} T_{lm,m'}^l / k$, (which has a physical meaning similar to that of the s-wave scattering length $a_{sc}$), are all nonvanishing asymptotically $k \to 0$. One can intuitively understand this property ($T_{lm,m'}^l \sim k$ in the low energy limit) based on the discussion of the $k$-dependence of the phase shifts of an asymptotic potential $-1/R^n$. We found that the couplings between different channels are essentially given by $V_2 \sim 1/R^6$. Thus, for each channel, the effective potential generated by the couplings, behaves in the limit of large $R$ as $1/R^6$. Therefore the character of the asymptotic $R$-dependence of the total effective potential for each partial wave equation is decided by the diagonal
part of the total potential. For \( l = 0 \) the effective potential behaves as \( 1/R^6 \) and so \( \delta_0 \sim k \). For \( l \neq 0 \) the effective potentials behave as \( 1/R^3 \) and so \( \delta_l \sim k \). The anisotropic nature required new numerical techniques to ensure the stability of the low energy scattering calculations. Detailed discussions of the complete T-matrix elements for all alkali metal atoms will be reported elsewhere [17].

Both the magnitude and sign of the \( t_{lm}^{l'm'} \) are tunable by changing \( E \) [8]. Quite generally, we found that within the same \( l \) and \( l' \) manifold the \( m = m' = 0 \) is always the largest \( t_{lm}^{l'm'} \) term, and the larger \( m \) and \( m' \), the smaller \( t_{lm}^{l'm'} \). Away from resonances, smaller \( l \) and \( l' \) correspond to larger \( t_{lm}^{l'm'} \). Such a situation allows for the general pairing schemes as in \(^3\)He [9,10,12]. One obtain the \( T = 0 \) gap equation (in the weak coupling limit),

\[
\mathcal{C}(\vec{k}) = \frac{4\pi \hbar^2}{M} \sum_{\vec{k'}} \sum_{lm} \sum_{l'm'} (4\pi) t_{lm}^{l'm'} Y_{lm}^*(\vec{k}) Y_{l'm'}(\vec{k'}) \frac{\mathcal{C}(\vec{k'})}{2E_{\vec{k'}}},
\]

where the general quasi-particle excitation spectra is

\[
E_{\vec{k}} = \sqrt{\epsilon_{\vec{k}}^2 + |\mathcal{C}(\vec{k})|^2},
\]

for the homogeneous case. \( \epsilon_{\vec{k}} = \frac{\hbar^2 k^2}{2M} - \epsilon_F \) is the bare particle energy (measured from the Fermi surface at \( \epsilon_F \)). Such a general pairing scheme results in an anisotropic gap \( \mathcal{C}(\vec{k}) \) and the excitation spectra \( E_{\vec{k}} \) [10,12]. In particular when one of the \( t_{lm}^{l'm'} \) is made dominant and attractive (positive), we can simplify the analysis by assuming

\[
\mathcal{C}_{lm}(\vec{k}) \approx \Delta_{lm} Y_{lm}^*(\vec{k}).
\]

One then obtains the \((T \neq 0)\) gap equation

\[
1 = \frac{4\pi \hbar^2}{M} \sum_{\vec{k'}} (4\pi) t_{lm}^{l'm'} |Y_{lm}(\vec{k})|^2 \frac{1}{2E_{\vec{k}}^2} \tanh \left( \frac{1}{2} \beta E_{\vec{k}} \right),
\]

with \( \beta = 1/k_B T \). At \( T_c, \Delta_{lm}(T_c) = 0 \), Eq. (10) can be approximately solved to give a result similar to [12],

\[
T_c \sim \frac{\epsilon_F}{k_B} \exp \left( -\frac{\pi}{2k_F |t_{10}|} \right),
\]

except for the substitution of \( V \rightarrow -t_{10}^{l'm'} \). The case of a p-wave pairing with \( t_{10}^{l'm'} \) being the dominant (and positive) term is indeed true for \(^6\)Li, \(^{40}\)K, and \(^{82,84,86}\)Rb in the maximum polarized state. These paired superfluid states are the analogues of the \(^3\)He in the \( A_1 \) phase.

Such a scheme is interesting since pairing involves only atoms in the same hyperfine state, yet the strength of the pairing can be as strong as that for a s-wave pairing in different hyperfine states [3,18]. This greatly increases the critical temperature for the BCS pairing to occur. The actual values of \( t_{lm}^{l'm'} \) are illustrated by our calculations in Figs. [1,2] and [3] for \(^6\)Li, \(^{40}\)K, and \(^{82,84,86}\)Rb respectively. Although hyperfine structures are not included
in these calculations presented. We expect they give the correct order of magnitude and the $E$-dependence since collisions among atoms in the maximum polarized state mainly proceed along the triplet potential curves. We have also estimated the critical temperatures Eq. (11) for typical trap parameters. They are plotted in dashed lines with respect to the logarithmic vertical axis to the right. The number density at the trap center is higher than the $10^{12}$ cm$^{-3}$ used for previous estimates, justified since all inelastic processes would be slower in our scheme, the same reason why the BEC was originally realized in similar maximum polarized states. In the maximum polarized states, the spin exchange collisional loss is eliminated and the two-body dipolar rates are suppressed. The three body loss inside an electric field is a much more complicated issue currently under investigation. This rate seems highly reasonable since the centrifugal barrier in the p-wave collision channel prevents close encounters of two atoms at short distances.

More generally, one may consider possibilities of pairing with $t^{1\pm 1}_{1\pm 1}$ terms if resonance structures can be induced. Such resonances may also provide larger $t^{m'}_{lm}$ values at smaller dc-E fields. We are currently pursuing detailed atomic collision calculations including hyperfine structures inside a dc-E to answer these questions. Inside an optical trap, different Zeeman states of the same hyperfine spin state are degenerate, but the effect of the dc-E can still be induced. In such a case one would expect that similar to the analysis of the Anderson-Brinkman-Morel states and Balian-Werthamer states in $^3$He, one can consider all kinds of spin symmetries of the paired atoms. This would represent a more interesting scenario than in the case of $^3$He because the total spins can be much larger, e.g. for $^{40}$K, $f = 9/2$ and $7/2$ respectively in the two ground hyperfine manifolds.

As illustrated in Fig. 1 for $^6$Li, within the range of dc-E field considered, the induced p-wave interaction is too weak for the BCS pairing to occur at reasonable temperatures. This is a result of the small electric polarizability of $^6$Li. However, for $^{40}$K (Fig. 2) and $^{82,84,86}$Rb (Fig. 3), pairing can be induced to occur at temperatures $\sim \hbar \omega_r/k_B$ for dc-E field of about 3,000 (kV/cm) and 1,000 (kV/cm) respectively. This should represent a reasonable prospect to aim for within current experimental capabilities. The estimate of $T_c$ is based on the numbers for currently available cylindrical magnetic traps (with $\omega_z = \lambda \omega_r$, where $\omega_z$ and $\omega_r$ are respectively the axial and radial frequencies), i.e. with the width of the trap ground state $a_r = \sqrt{\hbar / 2 M \omega_r} \gg |t^{m'}_{lm}|$. The Fermi energy and the momentum are respectively $\epsilon_F = \hbar \omega_r (6\lambda N)^{1/3}$ and $k_F = (6\lambda N)^{1/6}/a_r$ for a noninteracting fermi gas in these traps. The effective spatial density at the trap center is $n(\vec{r} = 0) \approx (\lambda N/6)^{1/3}/(\pi^2 a_r^3)$. Although the required electric field is high for a dc-E configuration, such field strengths can be easily achieved with lasers (e.g., CO$_2$ laser) in a quasi-static situation.
In conclusion, we have proposed a BCS pairing scheme for atoms inside an external dc-E. We have performed detailed atomic calculations demonstrating the strong anisotropic pairing interactions for polarized atoms. By turning the p-wave scattering amplitude to larger values, we can effectively tune (higher) the critical temperature $T_c$. Compared with the existing proposals, our scheme seems to have several distinct advantages: First, the pairing only involves atoms in the maximum polarized state. This allows the same phase space density to be reached at a lower spatial density, thus lowering three-body decays. Second, trapping inside the maximum polarized triplet hyperfine states completely eliminates the large (usually dominant) two-body decay mechanism: those due to spin exchange collisions. Additionally, it suppresses the two-body dipolar decay processes since the final decay channels are more restricted. Third, the applied dc-E provides a tuning knob for optimal experimental control. All indications seem to be consistent with our proposal at the moment. We therefore encourage experimentalists to attempt the implementation of the strong electric fields required. It may also become possible to utilize the low energy scattering resonances to induce dominant two-body attractions in d-, e-, and maybe even f-waves. If the fermionic gases can be confined in an optical dipole trap similar to those recently realized for BEC at MIT [10], one may be able to create more exotic BCS states such as those of the A- and B- phases in $^3$He, but with richer spin structures [12].

This work is supported by the ONR grant 14-97-1-0633 and by the NSF grant No. PHY-9722410. We want to thank Drs. R. Hulet and C. Green for providing triplet potentials for Li and Rb respectively. Most of the work was completed while L.Y. was a long term visitor to the Institute for Theoretical Physics (ITP). L.Y. would like to thank many enlightening discussions with participants of the ITP BEC workshop. In particular, he would like to thank Profs. J. Ho, M. Gunn, Y. Kagan, and A. J. Leggett for the discussion of BCS physics. He would also like to thank the ITP for its hospitality and the support of the NSF grant No. PHY94-07194 (to ITP).

APPENDIX A: SCATTERING FROM A ANISOTROPIC POTENTIAL

In this appendix we provide the essential formulation we developed for the scattering from the anisotropic potential containing the electric induced dipole-dipole interaction. As was shown in [8], the atom-atom interaction potential inside a dc electric field of strength $E$ is

$$V(\hat{R}) = V_0(R) + V_E(R), \quad (A1)$$

where $V_0$ is the symmetric part (for the usual collisional studies), and the induced anisotropic part is

$$V_E(R) = -\frac{C_E}{R^3} P_2(\cos \theta), \quad (A2)$$
where $C_E = 2\xi^2 \alpha_1^A(0)\alpha_1^B(0)$ is the electric induced dipole interaction coefficient and $\alpha_1^{A(B)}(0)$ are the static atomic dipole polarizabilities of atom A and B respectively, $P_2(\cos \theta)$ is the Legendre polynomial of order 2 and $\theta$ is the angle between the directions of the electric field and the internuclear axis.

With such a potential (A1), the usual partial wave expansion has to be modified. Consistent with the standard definition for the scattering amplitude, we denote the incident momentum (relative motion of the two atoms) by $\vec{k}$, then the scattering wave function to be computed is

$$\psi(\vec{r}) \sim e^{i\vec{k} \cdot \vec{r}} + \frac{f(\vec{k}, \hat{r})}{r} e^{i k r},$$  \hspace{1cm} (A3)

note, here $\hat{r}$ is the relative coordinates between the two nuclei. The scattering is described by $f(\vec{k}, \hat{r})$ which (for elastic scattering) is always on the energy shell, i.e. the scattering momentum $\vec{k}' = k \hat{r}$. We also expand the incident wave according to

$$e^{i\vec{k} \cdot \vec{r}} = 4\pi \sum_{lm} i^l j_l(kr) Y^*_{lm}(\hat{k}) Y_{lm}(\hat{r}),$$  \hspace{1cm} (A4)

with the asymptotic expansion,

$$j_l(kr) \sim \frac{1}{kr} \sin(kr - \frac{l\pi}{2}), \quad r \to \infty.$$  \hspace{1cm} (A5)

Therefore

$$e^{i\vec{k} \cdot \vec{r}} \sim \frac{4\pi}{kr} \sum_{lm} i^l \sin(kr - \frac{l\pi}{2}) Y^*_{lm}(\hat{k}) Y_{lm}(\hat{r}).$$  \hspace{1cm} (A6)

The scattering amplitude $f(\vec{k}, \hat{r})$ can also be expanded onto the (complete) basis $Y_{lm}(\hat{r})$ to yield

$$f(\vec{k}, \hat{r}) = \frac{4\pi}{k} \sum_{lm} T_{lm}(\hat{k}) Y_{lm}(\hat{r}).$$  \hspace{1cm} (A7)

We then have for the scattering solution

$$r \psi_{\vec{k}}(\vec{r}) = \phi_{\vec{k}}(\vec{r}) = \frac{4\pi}{k} \sum_{lm} i^l \left[ Y^*_{lm}(\hat{k}) \sin(kr - \frac{l\pi}{2}) + T_{lm}(\hat{k}) e^{i k r - i l \frac{\pi}{2}} \right] Y_{lm}(\hat{r}).$$  \hspace{1cm} (A8)

Therefore the solution $\phi_{\vec{k}}(\vec{r})$ can also be solved in the multi-channel $Y_{lm}(\hat{r})$ basis. We have the coupled equation,

$$H_l \phi_{lm}(\vec{r}) = \sum_{l'm'} i^{l-l'} \langle lm | V(\vec{r}) | l'm' \rangle \phi_{l'm'},$$  \hspace{1cm} (A9)

where here $H_l$ is the effective Hamiltonian for the l-th partial wave

$$h_l = -\frac{d^2}{dr^2} + \frac{l(l + 1)}{r^2}.$$  \hspace{1cm} (A10)

The boundary conditions for the scattering are as from Eq. (A8).
\[
\phi_{lm} \sim Y_{lm}^*(\hat{k}) \sin(kr - i\frac{\pi}{2}) + T_{lm}(\hat{k}) e^{ikr - i\frac{\pi}{2}}.
\] (A11)

Rewrite the total potential as
\[
V(\vec{r}) = V_0 + V_2 \sqrt{4\pi} Y_{20}(\vec{r}),
\] (A12)
with
\[
V_2(\vec{r}) = -\frac{C_3}{r^3} \sqrt{\frac{1}{5}},
\] (A13)
we obtain
\[
\langle lm | V(\vec{r}) | l'm' \rangle = V_0 \delta_{ll'} \delta_{mm'} + \delta_{mm'} V_2 \langle lm | 20 | l'm \rangle,
\] (A14)
and the final multi-channel form for the scattering equations
\[
h_l \phi_{lm}(r) = V_0 \phi_{lm}(r) + \sum_{l'} i^{l'-l} \langle lm | V(\vec{r}) | l'm' \rangle \phi_{l'm}(r).\] (A15)

Due to the symmetry of the matrix element
\[
\langle lm | 20 | l'm' \rangle = 0, \text{ if } l + l' = 2 = \text{odd}. \text{ We immediately see that the even and odd parity (l) channels decouple. Specifically, if we keep open only the lowest two channels, we obtain}
\[
\begin{cases}
h_0 \phi_{00}(r) = V_0 \phi_{00}(r) - V_2 \phi_{20}(r), \\
h_2 \phi_{20}(r) = (V_0 + \frac{2}{\sqrt{5}} V_2) \phi_{20}(r) - V_2 \phi_{00}(r),
\end{cases}
\] (A16)
and
\[
\begin{cases}
h_1 \phi_{10}(r) = (V_0 + \frac{2}{\sqrt{5}} V_2) \phi_{10}(r) - 3\sqrt{\frac{2}{15}} V_2 \phi_{30}(r), \\
h_3 \phi_{30}(r) = (V_0 + \frac{2}{\sqrt{5}} V_2) \phi_{30}(r) - 3\sqrt{\frac{2}{15}} V_2 \phi_{10}(r),
\end{cases}
\] (A17)
\[
\begin{cases}
h_1 \phi_{1\pm 1}(r) = (V_0 - \frac{1}{\sqrt{5}} V_2) \phi_{1\pm 1}(r) - 3\sqrt{\frac{2}{20}} V_2 \phi_{3\pm 1}(r), \\
h_3 \phi_{3\pm 1}(r) = (V_0 - \frac{1}{\sqrt{5}} V_2) \phi_{3\pm 1}(r) - 3\sqrt{\frac{2}{20}} V_2 \phi_{1\pm 1}(r).
\end{cases}
\] (A18)

To match the boundary conditions, we further expand the matrix scattering element according to
\[
T_{lm}(\hat{k})/k = \sum_{l'm'} t_{lm}^{l'm'}(k) Y_{l'm'}(\hat{k}).
\] (A19)

As discussed in detail in [8], the nature of the asymptotic dipole-dipole interaction potential is such that all \( t_{lm}^{l'm'}(k) \) become independent of \( k \) at low energies. Upon matching with the numerically integrated solutions, we obtain all \( t_{lm}^{l'm'}(k) \).

The total scattering amplitude is therefore
\[
f(\vec{k}, \vec{r}) = f_{\text{even}}(\vec{k}, \vec{r}) + f_{\text{odd}}(\vec{k}, \vec{r}).
\] (A20)

For identical particle scattering one has to worry about the symmetrized (anti-symmetrized) amplitude \( f_S (f_A) \) for bosons (fermions). In the spin triplet electronic state of two atoms, one has
\[ f_s(\vec{k},\hat{r}) = \frac{1}{\sqrt{2}} [f(\vec{k},\hat{r}) + f(\vec{k},-\hat{r})] = \sqrt{2} f_{\text{even}}(\vec{k},\hat{r}), \]  

(A21)

and

\[ f_A(\vec{k},\hat{r}) = \frac{1}{\sqrt{2}} [f(\vec{k},\hat{r}) - f(\vec{k},-\hat{r})] = \sqrt{2} f_{\text{odd}}(\vec{k},\hat{r}). \]

A similar scheme for $^{40}$K has been recently proposed by B. DeMarco and D. S. Jin, Phys. Rev. A 58, R4267 (1998).

M. Marinescu and L. You, (unpublished).

In an optical trap, an s-wave pairing is possible for atoms in spin anti-symmetric states Zeeman states. The spin symmetry is given by $(-1)^{2F+\ell}$ with $\vec{F} = \vec{\ell} + \vec{f}$ the total hyperfine spin. J. Ho and S. Yip, Phys. Rev. Lett. 82, 247 (1999); and Ref. [3].

For the CO$_2$ laser at a wavelength of $\lambda_L = 10.6$ (\(\mu\)m), the strength of the quasi-static electric field is given by $E \sim 27\sqrt{I}$ (V/cm), with laser intensity $I$ in units of (watts/cm$^2$). Therefore a field of $10^6$ (V/cm) requires $I \sim 10^9$ (watts/cm$^2$).

FIG. 1. For $^6$Li with $\lambda = 1$, $N = 10^6$, and $\omega_r = (2\pi)400$ (Hz). We then have $a_r = 1.45$ (\(\mu\)m), $\epsilon_F \approx 181.7 (\hbar\omega_r)$, $k_F \approx 13.5/a_r$, and $n(\vec{r} = 0) = 1.36 \times 10^{13}/\text{cm}^3$. The solid lines denote $t_{lm}$ in (a.u.) and refer to the left vertical scale, while the dashed line denotes $k_BT_c$ (for pairing with $\tau_{10}$) in units of $\hbar\omega_r$ and refers to the (10 based) logarithmic right vertical scale.

FIG. 2. The same as for Fig. 1, but now for $^{40}$K with $\lambda = 0.1$, $N = 10^6$, and $\omega_r = (2\pi)400$ (Hz). We then have $a_r = 0.56$ (\(\mu\)m), $\epsilon_F \approx 84.3 (\hbar\omega_r)$, $k_F \approx 9.2/a_r$, and $n(\vec{r} = 0) = 7.45 \times 10^{13}/\text{cm}^3$.

FIG. 3. The same as for Fig. 2, but now for $^{82,84,86}$Rb with $a_r \sim 0.39$ (\(\mu\)m) and $n(\vec{r} = 0) \sim 2.1 \times 10^{14}/\text{cm}^3$. All three isotopes give similar results since hyperfine structures are not included here. The half lifetimes of the three isotopes are 1.25 minute, 32.9, and 18.8 days respectively.
