Abstract

Mutations in the cytoplasmic tail (CT) of voltage gated sodium channels cause a spectrum of inherited diseases of cellular excitability, yet to date only one mutation in the CT of the human skeletal muscle voltage gated sodium channel (hNa\textsubscript{v}1.4\textsubscript{F1705I}) has been linked to cold aggravated myotonia. The functional effects of altered regulation of hNa\textsubscript{v}1.4\textsubscript{F1705I} are incompletely understood. The location of the hNa\textsubscript{v}1.4\textsubscript{F1705I} in the CT prompted us to examine the role of Ca\textsuperscript{2+} and calmodulin (CaM) regulation in the manifestations of myotonia. To study Na channel related mechanisms of myotonia we exploited the differences in rat and human Na\textsubscript{v}1.4 channel regulation by Ca\textsuperscript{2+} and CaM. hNa\textsubscript{v}1.4\textsubscript{F1705I} inactivation gating is Ca\textsuperscript{2+}-sensitive compared to wild type hNa\textsubscript{v}1.4 which is Ca\textsuperscript{2+} insensitive and the mutant channel exhibits a depolarizing shift of the V\textsubscript{1/2} of inactivation with CaM over expression. In contrast the same mutation in the rNa\textsubscript{v}1.4 channel background (rNa\textsubscript{v}1.4\textsubscript{F1698I}) eliminates Ca\textsuperscript{2+} sensitivity of gating without affecting the CaM over expression induced hyperpolarizing shift in steady-state inactivation. The differences in the Ca\textsuperscript{2+} sensitivity of gating between wild type and mutant human and rat Na\textsubscript{v}1.4 channels are in part mediated by a divergence in the amino acid sequence in the EF hand like (EFL) region of the CT. Thus the composition of the EFL region contributes to the species differences in Ca\textsuperscript{2+}/CaM regulation of the mutant channels that produce myotonia. The myotonia mutation F1705I slows I\textsubscript{Na} decay in a Ca\textsuperscript{2+}-sensitive fashion. The combination of the altered voltage dependence and kinetics of I\textsubscript{Na} decay contribute to the myotonic phenotype and may involve the Ca\textsuperscript{2+}-sensing apparatus in the CT of Na\textsubscript{v}1.4.

Introduction

Precise and coordinated activity of skeletal muscle results from highly regulated signals generated by the orchestrated activities of different ion channels. A spectrum of muscle disorders are caused by the mutations in different ion channels [1]. A number of mutations in different regions of the human voltage-gated Na channel, hNa\textsubscript{v}1.4 have been reported to cause skeletal muscle disorders [2]. Mutations in the transmembrane domains and linker regions cause cold aggravated myotonia [3,4,5,6] yet only one case of cold aggravated myotonia [7], has been linked to a mutation in the CT of the skeletal muscle sodium channel, hNa\textsubscript{v}1.4 (F1705I, Figure 1A) and functionally studied. The other mutation in the CT-Na\textsubscript{v}1.4, E1702K has been linked to paramyotonia congenita [8], but not functionally studied. Interestingly, another mutation Q1633E, causes potassium aggravated myotonia and is located in the EF hand like (EFL) region, that is the region in and around Helix 1, and the loop between Helix 1 and Helix 2 of the CT-hNa\textsubscript{v}1.4, and about 71 amino acids upstream of the E1705I mutation. Q1633E and F1705I have comparable electrophysiological effects including disruption of fast inactivation, slowed current decay, and a depolarized shift in the voltage dependence of availability [9]. hNa\textsubscript{v}1.4 mutations that cause myotonic disorders are associated with changes in the kinetics and voltage dependence of gating generally resulting in a gain-of-function.

There is substantial evidence that the CT of Na\textsubscript{v} channels regulate the kinetics and voltage dependence of inactivation [10,11,12,13]. Moreover, Ca\textsuperscript{2+} and CaM/CaM kinase (CaMK) distinctly modulate inactivation of different isoforms of Na\textsubscript{v} channels through interaction with structural motifs in the CT although the mechanisms are not fully understood [10,11,14,15,16,17,18]. There is evidence, particularly in HEK cells, that over expression of CaM will alter Na\textsubscript{v}1.4 channel gating [10,15,16], and this is not unique to this channel but it also observed for other voltage dependent channels [15,19,20]. An EFL sequence [21,22] in the CT of Na\textsubscript{v}1.5 and Na\textsubscript{v}1.1 has been shown to influence Ca\textsuperscript{2+} regulation of channel gating [14,17,18,23,24,25]. Other acidic residues in the H1–H2 loop of the proximal C-terminus of this region may affect Ca\textsuperscript{2+} sensitivity of channel gating as well [24,26], and the NMR solution and crystal structures in this region reveals binding of Ca\textsuperscript{2+} [24] or Mg\textsuperscript{2+} [27]. In addition to the EFL, sites in the III–IV linker are involved in Ca\textsuperscript{2+}/CaM mediated regulation of gating [28,29,30]. Similar Ca\textsuperscript{2+}/CaM sites are also present in the CT of Na\textsubscript{v}1.4; however, their roles in channel regulation and relevance to disease causing mutations of the CT-Na\textsubscript{v}1.4 are not known. The goals of this
study are to understand the pathogenesis of temperature sensitive myotonia caused by the F1705I mutation, and to use this naturally occurring mutation (and the species specific differences) to better understand the regulation of the NaV channels by Ca_{2+}. We demonstrate that the hNaV1.4F1705I alters the voltage dependence of inactivation and the temperature sensitivity of current kinetics. In addition, key residues in the EFL alter the CaM and Ca_{2+} dependence of channel gating which may also contribute to the myotonia phenotype.

Materials and Methods

Plasmid Construction

The EYFP fused channel construct NaV_{1.4}-EYFP was prepared as described previously [15]. The myotonia causing mutation in the rat CT, rNaV_{1.4}F1698I, was made by site directed mutagenesis using primer pairs:

Forward (F): 5’CATGGAGGAGAAGATTATGGCAGC-CAAC3’
Reverse (R): 5’GTTGGCTGCCATGAATATCTTCTCCTCCATG3’.

All the clones were sequence verified.

Transfection of Cells

Approximately 0.75 x 10^6 Human embryonic kidney cells (HEK293; American Type Culture Collection, Manassas, VA) were cultured in 6-well tissue culture dishes in DMEM supplemented with 10% FBS, L-glutamine (2 mmol/L), penicillin

Figure 1. Ca_{2+}-sensitivity of human NaV_{1.4}F1705I inactivation. (A) A schematic of the structured region of the C-terminus of hNaV_{1.4} between amino acids residues 1788 and 2040, the predicted helices are labeled H1–H6. The location of the EFL residues in and around H1 harbors species specific variations in the key Ca_{2+} sensing residues in hNaV_{1.4} (G1613S and A1636D) compared with the rat isoform. The CaM binding motif IQ in H6 and, the cold aggravated myotonia mutation F1705I (rat: F1698I) in H5 are illustrated. (B) Representative whole-cell currents through wild type and mutant hNaV_{1.4}F1705I channels expressed in HEK293 cells in [Ca^{2+}]_{free} conditions. Na^{+} currents were elicited by the protocol in the inset. (C) [Ca^{2+}] does not alter the I-V relationship of hNaV_{1.4}F1705I. (D) Representative steady-state inactivation currents from different holding potentials through mutant hNaV_{1.4}F1705I channels in the presence of 0.5 μM or absence of Ca^{2+}. (E) Activation and steady-state inactivation curves of wild type and hNaV_{1.4}F1705I channels in the absence and presence of 0.5 μM intracellular Ca^{2+}. The V_{1/2} of inactivation of hNaV_{1.4}F1705I is sensitive to [Ca^{2+}], and significantly shifted in the hyperpolarizing direction in the presence of Ca^{2+} (p<0.005). The activation relationships are fitted with dotted lines, the V_{1/2} of activation are unaffected by change in [Ca^{2+}]. (F) and (G) illustrate the window currents through wild type and hNaV_{1.4}F1705I in presence (F) and absence (G) of intracellular Ca^{2+}, respectively. Dotted lines represent the wild type channel. The symbols and color are the same in plots C, E, F, and G.

100 U/mL), and streptomycin (10 mg/mL). The cells were co-transfected with plasmids encoding the β1 subunit and the appropriate fluorescency–tagged Na\textsubscript{v}1.4 and CaM variants: human or rat wild type Na\textsubscript{v}1.4-EYFP, hNa\textsubscript{v}1.4F1705I-EYFP, rNa\textsubscript{v}1.4F1698I-EYFP, hNa\textsubscript{v}1.4F1705I+GA/MD-EYFP and ECFP-CaM or ECFP-CaM\textsubscript{1234} alone or in combination. Cells were
transfected using Lipofectamine™ 2000 (Invitrogen) according to the manufacturer’s instructions and were studied 48 to 72 hours post-transfection. The total amount of DNA for all transfections was kept constant.

**Electrophysiology**

HEK293 cells expressing wild type or mutant EYFP-tagged NaV1.4 channels were selected for recording. In some experiments, cells expressing both yellow and cyan fluorophores that were co-transfected with tagged NaV1.4 channel variants and CaM or CaM1234 were selected for patching. Cells were patch clamped with an Axopatch 200B patch-clamp amplifier using pipettes with tip resistances of 1–3 MΩ and typical series resistance compensation of >90% to minimize voltage clamp errors. Current recording was initiated 10 minutes after establishing whole-cell configuration, and currents were filtered at 5 kHz.

All the solutions used in this study were prepared as described previously [14,17,31,32]. The bath solution contained (in mmol/L): 145 NaCl, 4 KCl, 1.8 CaCl2, 1 MgCl2, 10 glucose and 10 Na-HEPES (pH 7.4). The Ca2+ free patch pipette solution contained (in mmol/L): 10 NaF, 100 CsF, 20 CsCl2, 20 BAPTA, 0 CaCl2 and 10 HEPES, pH adjusted to 7.35 with CsOH. The 0.5 mmol/L Ca2+ patch pipette solution contained (in mmol/L): 10 NaF, 100 CsF, 20 CsCl2, 5 BAPTA, 4 CaCl2 and 10 HEPES, pH adjusted to 7.35 with CsOH. The osmolarity of the bath and pipette solutions were equalized using glucose. The free [Ca2+] in the solutions was estimated with WEBMAX Standard software (http://www.stanford.edu/~cpatton/webmaxcalc.htm) and found to be about 0.5 μM. The free [Ca2+] in the solutions was verified by measurement using a Kwik-Tip Calcium ion-selective electrode (WPI) (Figure S1 and Table S1 in File S1). We studied the effect of intracellular Ca2+ on the voltage dependence of inactivation gating of hNaV1.4 with chloride substituted for fluoride in the pipette solution and found no significant difference in the Ca2+ sensitivity of gating (Figure S2 in File S1).

Standard two-pulse protocols were used to generate the steady-state inactivation curves. The voltage dependence of steady-state fast inactivation was studied using 500 ms inactivation pre-pulses over a voltage range from −140 to +30 mV in steps of 5 mV, followed by a 50 ms test pulse at −20 mV. Currents were normalized to the maximal current (I_{max}) and fit to a Boltzmann function of the form (\gamma = [(A_1-A_2)/(1+e^{x-x_0/d})]+A_2) to determine the membrane potential eliciting half-maximal inactivation (V_{1/2}), where A_1 and A_2 are maximum and minimum availabil-

Results

hNa\(_{\text{V}}\)1.4/4F1705I Alters Current Kinetics and Gating

A mutation (F1705I) in the structured portion of the CT of hNa\(_{\text{V}}\)1.4 has been associated with cold aggravated myotonia (Figure 1A). We studied the effect of hNa\(_{\text{V}}\)1.4/4F1705I on channel function by transient expression in HEK293 cells at RT. Currents through wild type hNa\(_{\text{V}}\)1.4 and hNa\(_{\text{V}}\)1.4/4F1705I channels were elicited by a family of depolarizing pulses ranging from –100 mV to +80 mV from a holding potential of –120 mV. Exponential functions of the form \(y = y_0 + Ae^{-x/t}\) were fitted to recovery data to determine time constants (\(t_{\text{rec}}\)), where \(y_0\) is the offset and \(A\) is amplitude. Significance was assessed using unpaired student’s t-test (Microcal Origin, Microcal Software Inc. MA), and \(p<0.05\) was considered significant.

Ca\(^{2+}\) \(\sim\) 73.5±1.0 mV and \(V_{1/2}\) hNa\(_{\text{V}}\)1.4/4F1705I: –62.7±0.1 mV, \(p<0.001\); Figure 1E and Table 1). In the absence of a significant shift in the activation curve this produces a significant increase in the window current of hNa\(_{\text{V}}\)1.4/4F1705I compared to wild type hNa\(_{\text{V}}\)1.4 in the presence or absence of [Ca\(^{2+}\)], (Figures 1F and 1G). Thus, hNa\(_{\text{V}}\)1.4/4F1705I destabilizes steady-state inactivation and increases window current; however, the mechanism by which the mutation produces altered voltage dependence of gating is unknown. Given the importance of the CT of Na\(_{\text{V}}\) channels in the regulation of gating by Ca\(^{2+}\)/CaM signaling we assessed whether hNa\(_{\text{V}}\)1.4/4F1705I interfered with channel modulation by Ca\(^{2+}\) or CaM.

hNa\(_{\text{V}}\)1.4/4F1705I Alters Ca\(^{2+}\) Sensitivity

Intracellular Ca\(^{2+}\) has been shown to regulate the cardiac isoform of Na\(_{\text{V}}\) channels, Na\(_{\text{V}}\)1.5. It is not yet known if [Ca\(^{2+}\)], similarly regulates skeletal muscle Na\(_{\text{V}}\)1.4 channels and if mutations in the CT of the channel affect Ca\(^{2+}\) regulation. In order to understand Ca\(^{2+}\) mediated regulation of hNa\(_{\text{V}}\)1.4 and hNa\(_{\text{V}}\)1.4/4F1705I we measured Na\(^{+}\) currents with 20 mM BAPTA in the pipette solution to create the Ca\(^{2+}\)-free intracellular condition. The I-V relationships of wild type hNa\(_{\text{V}}\)1.4 and hNa\(_{\text{V}}\)1.4/4F1705I are almost identical (Figure 1C); and the \(V_{1/2}\) of the activation (G–V) curves were unchanged in the absence of Ca\(^{2+}\) (Figure 1E and Table 1). The decay rate of wild type hNa\(_{\text{V}}\)1.4 was insensitive to the intracellular [Ca\(^{2+}\)]. The decay of hNa\(_{\text{V}}\)1.4/4F1705I currents is up to 2.5 times slower in the absence of Ca\(^{2+}\) compared to 0.5 μM [Ca\(^{2+}\)], (Figures 2A, 2B and Table 2). The decay of hNa\(_{\text{V}}\)1.4/4F1705I currents with 20 mM BAPTA at RT in both low and 0.5 μM [Ca\(^{2+}\)], (Figures 2A, 2B and Table 2). We studied the effect of hNa\(_{\text{V}}\)1.4/4F1705I on current decay at 37°C, as patients with the mutation do not exhibit myotonia at normal body temperature. In contrast to RT, at 37°C in 0.5 μM [Ca\(^{2+}\)], the current decay of hNa\(_{\text{V}}\)1.4/4F1705I is markedly hastened (Figure 2C) and is not significantly different from wild type except at –30 mV (Figures 2C, 2D, and Table 2). At 37°C the \(V_{1/2}\) of steady-state inactivation of hNa\(_{\text{V}}\)1.4/4F1705I was significantly shifted in hyperpolarizing direction compared to RT (\(V_{1/2}\) at 37°C: –71.6±0.1 mV and \(V_{1/2}\) at RT: –62.7±0.1 mV, \(p<0.001\); Figure 2E). In Ca\(^{2+}\), decay, particularly at negative voltages, results from both inactivation and deactivation. We found no significant difference in the rates of deactivation at voltages between –180 and –100 mV (\(p<0.05\); Figure S3 in File.

Table 2. Na current decay time constants of hNa\(_{\text{V}}\)1.4 and myotonia mutant hNa\(_{\text{V}}\)1.4/4F1705I.
However, at voltages from −90 mV to −60 mV, \( \tau_{\text{Deactivation}} \) of hNa\( \text{V}_{1.4} \) in the Ca\( ^{2+} \)-free condition is significantly larger than in the wild type channel, with or without Ca\( ^{2+} \) (\( p<0.05 \); Figure S3 in File S1).

Our previous work showed that the cardiac isoform hNa\( \text{V}_{1.5} \) is [Ca\( ^{2+} \)]\( _{i} \) sensitive, and lowering intracellular Ca\( ^{2+} \) shifts the \( V_{1/2} \) of steady-state fast inactivation of hNa\( \text{V}_{1.5} \) in hyperpolarizing direction [14]. However, hNa\( \text{V}_{1.4} \) was insensitive to [Ca\( ^{2+} \)]\( _{i} \) and altering [Ca\( ^{2+} \)]\( _{i} \) does not significantly affect the voltage dependence of steady-state inactivation of wild type hNa\( \text{V}_{1.4} \) channels (Figure 1E). In contrast, the \( V_{1/2} \) of steady-state inactivation of hNa\( \text{V}_{1.4} \) in the absence of intracellular Ca\( ^{2+} \) compared with the 0.5 mM [Ca\( ^{2+} \)]\( _{i} \) (Figures 1D, 1E and Table 1). Thus hNa\( \text{V}_{1.4} \) exhibits Ca\( ^{2+} \) sensitivity of steady-state inactivation.

Figure 3. CaM-induced shift of inactivation in hNa\( \text{V}_{1.4} \) channels. Representative Na\( ^{+} \) currents and I–V relationships for wild type (A) and hNa\( \text{V}_{1.4} \) channels (B) elicited by the same pulse protocol shown in the inset of Figure 1B. CaM and CaM\(_{1234}\) over expression significantly (\( p<0.05 \)) shifts the wild type but not the hNa\( \text{V}_{1.4}_F_{1705I} \) I–V in the depolarizing direction. (C) Representative steady-state inactivation currents elicited from different holding potentials. (D, E) Plots of the steady-state inactivation and activation relationships of wild type hNa\( \text{V}_{1.4} \) (D) and hNa\( \text{V}_{1.4}_F_{1705I} \) channels (E). The solid lines are the fits to steady-state inactivation data with CaM and CaM\(_{1234}\) over expression. There is a significant (\( p<0.005 \)) depolarizing shift of the inactivation curve by CaM and CaM\(_{1234}\) compared to the expression of hNa\( \text{V}_{1.4}_F_{1705I} \) alone. The symbols and colors are the same in all panels of the figure. doi:10.1371/journal.pone.0081063.g003

Figure 4. Ca\( ^{2+} \) regulation of the rat Na\( \text{V}_{1.4} \). Whole-cell rNa\( \text{V}_{1.4} \) and rNa\( \text{V}_{1.4}_F_{1698I} \) expressed currents (A) are not affected by [Ca\( ^{2+} \)]\( _{i} \). (B) The voltage dependence of activation (dotted lines) and steady-state inactivation (solid lines) of rNa\( \text{V}_{1.4} \). (C) rNa\( \text{V}_{1.4}_F_{1698I} \) significantly (\( p<0.05 \)) shifts the activation and inactivation curves in the depolarizing direction and eliminates the sensitivity of inactivation to changes in [Ca\( ^{2+} \)]\( _{i} \). The dotted lines represent the wild type channel in the absence of [Ca\( ^{2+} \)]\( _{i} \). The symbols are the same in plots B and C. doi:10.1371/journal.pone.0081063.g004

Distinct from wild type hNaV1.4 which is insensitive to changes in [Ca\(^{2+}\)].

hNaV1.4 \(_{F1705I}\) Alters CaM Modulation

The F1705I mutation which is remote from the EFL region modifies the Ca\(^{2+}\) sensitivity of gating. F1705 is predicted to be in Helix 5 of the CT hNaV1.4 and is closer in the linear amino acid sequence to the CaM binding IQ motif in Helix 6 (Figure 1A). Previously we have shown that CaM binds to the IQ motif and shifts the voltage dependence of inactivation of rat Na\(_V\)1.4 (rNa\(_V\)1.4) and Ca\(^{2+}\) binding-deficient hNaV1.4 channels that are mutated in the EFL [10,14,15]. We tested the hypothesis that the large changes in Na\(^{+}\) current inactivation exhibited by hNaV1.4 \(_{F1705I}\) compared to wild type hNaV1.4 are due to functional alterations in CaM interaction with the IQ motif. We examined the effects of CaM over expression on hNaV1.4 \(_{F1705I}\) and wild type hNaV1.4 gating. As Ca\(^{2+}\) can bind to CaM and modulate channel gating, we also studied effect of Ca\(^{2+}\) binding deficient CaM or apo-CaM (CaM1234) to delineate direct effects of Ca\(^{2+}\) on the channel compared to Ca\(^{2+}\) effects through CaM. In contrast to the wild type rat Na\(_V\)1.4 channel [15], over expression of both CaM and CaM1234 with wild type human Na\(_V\)1.4 shifts the channel’s I-V relation in the depolarizing direction in 0.5 \(\mu\)M [Ca\(^{2+}\)] (Figure 3A and Table 1). Co-expression of CaM and CaM1234 with hNaV1.4 significantly shifts the voltage dependence of activation in the depolarizing direction (Figure 3D). In contrast, neither the I-V relationships or voltage dependence of activation of hNaV1.4 \(_{A1703I}\) were affected by co-expression with CaM or CaM1234 (Figures 3B, 3E and Table 1).

We previously demonstrated that CaM is tethered to the CT of Na\(_V\)1.4, and CaM binding to the IQ motif shifts the steady-state inactivation of the rat isoform in a hyperpolarizing direction [10,15] (Table 1). In contrast, co-expression of CaM with hNaV1.4 significantly shifts wild type channel availability in the depolarizing direction in 0.5 \(\mu\)M [Ca\(^{2+}\)] (Figures 3C and D) and in the hyperpolarizing direction in the Ca\(^{2+}\) free intracellular condition, when compared with the absence of exogenous CaM (Table 1; \(p<0.05\)). CaM1234 over expression in 0.5 \(\mu\)M [Ca\(^{2+}\)] shifts the V\(_{1/2}\) of inactivation of hNaV1.4 in the depolarizing direction compared to the absence of CaM1234 (Figure 3D; \(p<0.05\)). Upon removal of [Ca\(^{2+}\)], the V\(_{1/2}\) of inactivation of hNaV1.4 is not affected by CaM1234 over expression (Table 1; \(p>0.05\)). Co-expression of CaM or CaM1234 with the mutant, hNaV1.4 \(_{F1705I}\) also significantly shifts channel availability in the depolarizing direction compared to the absence of CaM co-expression (Figures 3C, 3E and Table 1; \(p<0.05\)). Similar to wild type, in Ca\(^{2+}\) free conditions, CaM or CaM1234 co-expression shifts V\(_{1/2}\) of steady-state inactivation in the hyperpolarizing direction (Table 1; \(p<0.05\)). Notably, in Ca\(^{2+}\) free conditions the CaM-induced hyperpolarizing shifts of steady-state inactivation of the wild type and mutant hNaV1.4 channels are in same direction as in the rat Na\(_V\)1.4 channel.

We speculate that the difference in the voltage dependence of gating of wild type human and rat Na\(_V\)1.4 channels when co-expression with Ca\(^{2+}\)-CaM/apo-CaM [15] may provide insights into the mechanisms of the Ca\(^{2+}\) modulation of channel function in the myotonia mutation and in wild type channels.

Effect of rNa\(_V\)1.4 \(_{F1698I}\) on Ca\(^{2+}\)/CaM Regulation of Channel Gating

The wild type rat and human isoforms of Na\(_V\)1.4 exhibit distinct differences in gating and regulation by Ca\(^{2+}\) and CaM. The orthologous mutation of hNa\(_V\)1.4 \(_{F1703I}\) in the rat is rNa\(_V\)1.4 \(_{F1698I}\). The activation curve of rNa\(_V\)1.4 \(_{F1698I}\) is significantly (\(p<0.05\)) shifted in the depolarizing direction (~+42 mV) compared to wild type rNa\(_V\)1.4 in 0.5 \(\mu\)M [Ca\(^{2+}\)] (Figures 4A, 4B and Table 1). In contrast to rNa\(_V\)1.4 \(_{F1698I}\), no activation shift was seen with the F1705I mutation in human Na\(_V\)1.4 (Figure 1E). Similar shifts in the activation curves of other Na\(_V\)1.4 mutants that cause myotonia have previously been reported [34,35,36].

We next examined whether Ca\(^{2+}\) altered rNa\(_V\)1.4 \(_{F1698I}\) gating. The V\(_{1/2}\)s of the activation of both the wild type rNa\(_V\)1.4 and rNa\(_V\)1.4 \(_{F1698I}\) were not different in 0.5 \(\mu\)M Ca\(^{2+}\) compared with the absence of Ca\(^{2+}\) (Figures 4B, C and Table 1).

Unlike wild type rNa\(_V\)1.4, the voltage dependence of the steady-state inactivation of rNa\(_V\)1.4 \(_{F1698I}\) was not affected by the [Ca\(^{2+}\)], (Figures 4B, C and Table 1). Neither rNa\(_V\)1.4 nor rNa\(_V\)1.4 \(_{F1698I}\) exhibit Ca\(^{2+}\) sensitivity to recovery from inactivated states (Table 1). Thus the Ca\(^{2+}\) sensitivity of steady-state inactivation of rNa\(_V\)1.4 was eliminated with a mutation remote in the linear amino acid sequence from the EFL motif. Although the rNa\(_V\)1.4 \(_{F1698I}\) results in loss of Ca\(^{2+}\) sensitivity of the channel, it also dramatically affects steady-state inactivation of the channel producing approximately ~+15 mV shift of the V\(_{1/2}\) compared to

---

**Figure 5. CaM shifts inactivation of rat Na\(_V\)1.4 \(_{F1698I}\).** (A) Representative families of rNa\(_V\)1.4 \(_{F1698I}\) activation currents co-expressed with either CaM or CaM1234. (B) Representative steady-state inactivation currents elicited from different holding potentials through rNa\(_V\)1.4 \(_{F1698I}\) channels in presence and absence of CaM over expression. (C) Activation and steady-state inactivation relationships. The solid lines are the fits to steady-state inactivation data of rNa\(_V\)1.4 \(_{F1698I}\) with CaM and CaM1234 over expression. There is a significant (\(p<0.05\)) shift of the inactivation curve by CaM compared to the expression of rNa\(_V\)1.4 \(_{F1698I}\) alone. Over expression of CaM1234 has no significant effect compared with the absence of CaM over expression. In contrast, the V\(_{1/2}\) of activation of rNa\(_V\)1.4 \(_{F1698I}\) is not changed by co-expression of CaM or CaM1234. The dotted lines in panel (C) represent wild type channel in 0.5 \(\mu\)M Ca\(^{2+}\).

IQ-CaM Interaction is Unaffected by rNaV1.4F1698I

The significant alteration in Na$^{+}$ current properties demonstrated by rNaV1.4F1698I suggests the possibility of a disruption of CaM interaction with the IQ motif which is in vicinity of F1698. CaM or CaM$_{1234}$ co-expression does not alter the current kinetics (Figure 5A) or the voltage dependence of activation of rNaV1.4F1698I (Figure 5C). Similarly, CaM and CaM$_{1234}$ do not affect the activation of wild type rNaV1.4 (Table 1). However, co-expression of CaM with rNaV1.4F1698I significantly shifts channel availability in the hyperpolarizing direction compared to the absence of CaM co-expression (Figures 5B and 5C; p<0.05). CaM$_{1234}$ has no effect on the voltage dependence of steady-state inactivation in 0.5 μM Ca$^{2+}$ (Figure 5C). CaM and CaM$_{1234}$ also have similar effects on wild type rNaV1.4 availability (Table 1).

The time constants of recovery from inactivated states of rNaV1.4F1698I are unaffected by over expression of CaM or CaM$_{1234}$ (Table 1). In both species the orthologous myotonia mutations in the CT affect the Ca$^{2+}$ regulation of channel gating. In the rat channel rNaV1.4F1698I abolished the Ca$^{2+}$ sensitivity observed in the wild type rNav1.4. In contrast, hNav1.4F1705I imparts sensitivity to Ca$^{2+}$ which is absent in wild type hNav1.4. We postulated that differences in the EFL region of the two channels contribute to the difference in Ca$^{2+}$ response of the orthologous myotonia mutations in the human and rat channels.

EFL Residues Mediate the Differences in Ca$^{2+}$ Regulation

We compared the amino acid sequences in the CT of the rat and human NaV1.4 channels in the EFL and IQ motifs. In the region that includes the EFL (Figure 1A), the amino acids at positions 1613 and 1636 in hNaV1.4 are glycine (G) and alanine (A), and the corresponding residues in rNaV1.4 are serine (S) and aspartic acid (D) respectively (Figure 6A). Position 1613 is within the predicted EFL region whereas residue 1636 is outside the EFL in H1–H2 loop region. We tested the hypothesis that hNav1.4F1705I altered channel gating by disruption of Ca$^{2+}$

---

**Figure 7. Ca$^{2+}$ sensitivity, inactivation gating and calmodulation.** This schematic illustrates the relationship between the Ca$^{2+}$ sensitivity of inactivation gating and the effect of CaM over expression. Channel variants that exhibit shifts in the voltage dependence of inactivation as a function of changes in intracellular [Ca$^{2+}$] exhibit a depolarized $V_{1/2}$ compared with variants insensitive to Ca$^{2+}$. The Ca$^{2+}$ sensitivity is associated with the direction of the gating shift induced by CaM over expression. Residues in the EFL are key determinants of the Ca$^{2+}$ sensitivity and effect of CaM over expression on inactivation gating. The red curves in plots indicate steady-state inactivation in the presence of CaM.

doi:10.1371/journal.pone.0081063.g007
sensing through the EFL motif. We generated a triple mutant human channel, containing F1705I and replacing the non-conserved residues in the human EFL with the corresponding amino acids from the rat sequence hNaV1.4/F1705I,G1613S,A1636D (hNaV1.4/F1705I,GS/AD) and hNaV1.4/F1705I,AD and hNaV1.4 have comparable peak current I–V relationships, and in both cases the voltage dependences of activation were not altered by the absence or presence of 0.5 mM Ca^{2+} (Figures 6B, 6C and Table 1). Similar to rNaV1.4/F1698I, steady-state inactivation of hNaV1.4/F1705I,GS/AD was insensitive to changes in the [Ca^{2+}] (Figure 6D and Table 1). Thus key residues in the EFL region contributed to the species differences in Ca^{2+} sensitivity of mutations in NaV1.4 that produce myotonia.

Remarkably hNaV1.4/F1705I,GS/AD exhibits CaM regulation that recapitulates that of rNaV1.4/F1698I. Over expression of CaM with hNaV1.4/F1705I,GS/AD produces a hyperpolarizing shift in V_{1/2} of steady-state inactivation compared to the mutant channel in the absence of CaM over expression (Figures 6E, 6F and Table 1; p<0.05). Similar to rNaV1.4/F1698I, CaM_{1234} over expression with hNaV1.4/F1705I,GS/AD does not alter the voltage dependence of steady-state inactivation compared to the mutant channel without CaM_{1234} over expression (Figure 6F and Table 1). The orthologous myotonia mutation on the rat channel background exhibits changes in Ca^{2+}/CaM regulation that are completely different from that of hNaV1.4/F1705I. However substituting the EFL residues present in the rat channel into the hNaV1.4/F1705I background is sufficient to recapitulate the Ca^{2+}/CaM regulation exhibited by rNaV1.4/F1698I (Figures 6 and Table 1). This holds true for wild type channels, as mutation of the non-conserved amino acids of the wild type hNaV1.4 EFL to match that of the rat sequence (G1613S and A1636D) reestablished Ca^{2+} and CaM sensitivity of inactivation gating mimicking that of wild type rat NaV1.4 (Figures 6G and 6H, Table 1). Additionally, changing the EFL residues (G and A) from human channel into the wild type rat NaV1.4 (rNaV1.4,GS/DA) or mutant rNaV1.4/F1698I (rNaV1.4/F1698I,GS/DA) background restored Ca^{2+}/CaM regulation similar to that displayed by hNaV1.4 or hNaV1.4/F1705I respectively (Table 1). Thus the differences in the key amino acids in the EFL region are associated with species-specific differences in Ca^{2+}/CaM regulation of the wild type and mutant, human and rat NaV1.4 channels.

**Discussion**

Myotonic mutations in hNaV1.4 have been reported to affect Na^{+} current inactivation properties. Wu et al. demonstrated a destabilization of fast inactivation without significant changes in activation or slow inactivation by the F1705I mutation [7]. However, the mechanism of the change in gating is uncertain as is the role of alteration of Ca^{2+} or CaM modulation of the function of the mutant channel. We have demonstrated that the CT myotonia mutation, hNaV1.4/F1705I slows the I_{Na} decay, depolarizes the voltage dependence of inactivation and augments the window current, effects that may contribute to the cold-induced myotonic phenotype. Notably, hNaV1.4/F1705I imparts intracellular Ca^{2+} sensitivity to inactivation gating, a feature that is distinct from the wild type hNaV1.4. However, the direction of the shift of steady-state inactivation of hNaV1.4/F1705I channels is opposite to the direction of the Ca^{2+}-induced shift observed with cardiac channel, hNaV1.1.5 [14]. Our data suggest that two key residues in the EFL (Figure 6, Table 1) modify gating of wild type hNaV1.4 and the myotonia mutant hNaV1.4/F1705I.

Sodium channel mediated myotonia is characterized electrophysiologically by a delay in inactivation that predisposes to repetitive depolarization and contraction of skeletal muscle after a brief stimulus. Previous studies suggested that a defect in fast inactivation, as in the CT mutant F1705I mutation, was sufficient to produce myotonia [7,37]. Our data shows, that along with a depolarizing shift in steady-state inactivation and slowed I_{Na} decay, reduced intracellular Ca^{2+} levels exaggerate both the depolarizing shift of inactivation (Figures 1D, 1E and 1G) and the slowing of I_{Na}, decay of the current (Figures 2A and 2B). It appears that the largest effect of the F1705I mutation is on the voltage dependence and temperature sensitivity of gating but our data suggest that altered [Ca^{2+}], sensitivity of the mutant channel potentiates symptoms of myotonia at low temperature. The experiments were designed to test the effects of Ca^{2+} on channel gating and we explored the extremes of the range of concentrations. We do not believe that bulk Ca^{2+} levels ever reach these levels but sub cellular distribution of ion concentrations are heterogeneous and local changes in Ca^{2+} in this range are feasible [38].

Slowing of I_{Na} decay, increased window current, altered voltage dependence of inactivation, along with disruption of Ca^{2+} sensitivity of hNaV1.4/F1705I could explain myotonia, but it is not clear what triggers cold-induced symptoms or why these patients are free from symptoms at normal body temperature. Our study indicates hastening of I_{Na} decay of hNaV1.4/F1703 at normal body temperature eliminates current changes that are associated with the myotonic phenotype. At 37 °C, the I_{Na} decay of hNaV1.4/F1703 (at −30 mV) is ∼5 times faster than at RT and is nearly identical to the decay rate of wild type hNaV1.4 current at 37 °C (Figures 2C and 2D). Additionally, at 37 °C, V_{1/2} of steady-state inactivation of hNaV1.4/F1703 significantly shifted ∼10 mV in hyperpolarizing direction compared to RT, and is comparable to V_{1/2} of wild type channel at RT (Figure 2E). The temperature dependent shift we observed in the human mutant channel is more than the previously reported ∼3 mV temperature dependent shift in steady-state inactivation of native rat skeletal muscle Na channels [39]. Rescue of I_{Na} decay and steady-state inactivation at 37 °C could explain why the patients with the F1705I mutation are free from myotonia at normal body temperature. Slowing of deactivation of hNaV1.4 may cause sustained skeletal muscle contraction by delaying repolarization thereby prolonging action potential duration [34]. Differential temperature-induced changes in mutant channel gating; particularly slowing of deactivation resulting in persistent membrane depolarization has been proposed for some hNaV1.4 mutations causing myotonia [40]; however, the F1705I mutation does not alter deactivation [33]. Additionally, it has been suggested that at normal temperatures more wild type channels are activated compared to mutant channels and with lowering of temperature mutant channels dominate membrane excitability [41]. Alternatively changes in temperature may be associated with changes in intracellular [Ca^{2+}] [42] that exaggerate the inactivation gating defects of the mutant channel. We speculate that temperature sensitive changes in intracellular Ca^{2+} could alter cold aggravated myotonia in F1705I mutant muscle.

The biophysical effects of hNaV1.4/F1705I and the orthologous rat mutation rNaV1.4/F1698I are consistent with a key role for the CT in inactivation gating. Resides in and around the EFL motif [21,22] of the CT of hNaV1.5 and NaV1.1 regulate the Ca^{2+} sensitivity of channel gating [14,17,18,23,24,25], which may occur at low levels of free [Ca^{2+}] in the cell [43]. In addition to the EFL, sites in the III-IV linker are involved in Ca^{2+}/CaM mediated regulation of gating [28,29]. We exploited the differences in the EFL sequences and Ca^{2+} sensitivity of inactivation gating of the human and rat orthologous NaV1.4 channels to better understand
the mechanisms of Ca\textsuperscript{2+} modulation of wild type and mutant channels. Inactivation gating of hNa\textsubscript{V1.4}F\textsubscript{1705I} is sensitive to changes in intracellular [Ca\textsuperscript{2+}], in contrast wild type hNa\textsubscript{V1.4} exhibits no such sensitivity to Ca\textsuperscript{2+}. The inverse is true for the wild type and mutant rat isoforms of Na\textsubscript{V}1.4. Mutating the non-conserved amino acids of the hNa\textsubscript{V1.4} EFL region to match that of the rat sequence (G1613S and A1636D), abolishes the Ca\textsuperscript{2+} sensitivity of hNa\textsubscript{V1.4}F\textsubscript{1705I}\textsubscript{GS/AD} mimicking that of rNa\textsubscript{V1.4}F\textsubscript{1698I}. Similarly, mutating the non-conserved amino acids of the wild type hNa\textsubscript{V1.4} EFL region to match that of the EFL residues consistently alter the Ca\textsuperscript{2+} sensitivity of the channel mimicking that of wild type rat Na\textsubscript{V}1.4 (Figures 6G, 6H, Table 1). To our knowledge, this is the first report of a mutation in the CT remote from the EFL region that abolishes Ca\textsuperscript{2+} sensitivity of gating of Na\textsubscript{V}1.4 channels; however, it is not clear that the rNa\textsubscript{V1.4}F\textsubscript{1698I} or hNa\textsubscript{V1.4}F\textsubscript{1705I} has compromised channel gating through a long range conformational effect on the EFL motif. Notably, both rat and human myotonic mutant channels dramatically shift the voltage dependence of inactivation gating in the depolarizing direction. A similar depolarizing shift in inactivation due to a mutation in the CT hNa\textsubscript{V1.4} (Q1633E) has been reported, implicating the EFL region of the CT in inactivation gating [9]. Thus it may be that these mutants introduce a significant local structural change in the predicted H5 which in turn influences the neighboring H4 and alters helical interactions in the EFL leading to a disruption of Ca\textsuperscript{2+} sensing. Hydrophobic helical interactions in the cardiac Na\textsubscript{V}1.5 EFL, particularly H1–H4, appear to stabilize the structure of the proximal CT of the channel which is postulated to be a prerequisite for durable inactivation [44]. Although most of the mutations at the hydrophobic interfaces of the EFL helices shift inactivation in the hyperpolarizing direction, there are important exceptions to this generalization [44]. The mechanism of the Ca\textsuperscript{2+} regulation of gating by residues in the CT is not fully understood and the role of direct Ca\textsuperscript{2+} binding to this region is debated. In fact the crystal structure of a ternary sequence (G1613S and A1636D) restores the Ca\textsuperscript{2+} sensitivity of hNa\textsubscript{V1.4}F\textsubscript{1705I}\textsubscript{GS/AD} of Na\textsubscript{V}1.4. Mutating the non-conserved amino acids of the hNa\textsubscript{V1.4} EFL region to match that of the rat sequence (G1613S and A1636D) restores the Ca\textsuperscript{2+} sensitivity of CaM over expression (Figure 7).

## Conclusion

The cold aggravated myotonia mutation, hNa\textsubscript{V1.4}F\textsubscript{1705I} in the CT of the skeletal muscle channel remote from the EFL region produces temperature-dependent slowing of current decay and significant destabilization of inactivation, and is associated with a disruption or alteration of Ca\textsuperscript{2+} regulation. Alteration of [Ca\textsuperscript{2+}]\textsubscript{i} sensitivity at low temperature could potentiate myotonia symptoms. These changes result in greater Na current availability at depolarized voltages, and thus prolongation of the cellular action potential which is likely to be the proximate cause of myotonia. Moreover the data suggests a mechanism by which drugs that stabilize Na current inactivation may be useful in controlling muscle symptoms. This disease causing mutation and isoform specific amino acid variation in the CT EFL provide important insights into the differences in Ca\textsuperscript{2+} regulation of Na\textsubscript{V}1.4 channels.

## Supporting Information

**File S1** Includes Methods, Figures S1 – S3 with legends, Table S1, and References. (DOCX)

## Acknowledgments

Dr Tomaszelli holds the Michel Mirowski MD Professorship in Cardiology at Johns Hopkins University. Yauli Tian and Victoria Halperin provided technical assistance.

## Author Contributions

Conceived and designed the experiments: SB GFT. Performed the experiments: SB. Analyzed the data: SB GFT. Contributed reagents/materials/analysis tools: SB GFT DAD PD. Wrote the paper: SB GFT DAD PD. Provided technical assistance, design and creation of expression constructs: DAD PD. Did the data interpretation: SB GFT.
