VYSKOCIL A, SMEJKALOVA J, TEJRAL J, EMMINGER S, VINCENTOVA M, ETTLEROVA E, LAUWERYS R, BERNARD A. Lack of renal changes in stainless steel welders exposed to chromium and nickel. Scand J Work Environ Health 1992;18:252—6. Biochemical markers of kidney damage were examined in 52 male stainless steel welders (manual metal arc welding) exposed to chromium and nickel. No difference was found in the mean urinary excretion of total proteins, albumin, protein 1, transferrin, retinol-binding protein, lactate dehydrogenase, lysozyme, or beta-N-acetylglucosaminidase in a comparison with matched referents. Beta2-microglobulin was slightly increased in those welders with a urinary chromium concentration of >64.5 nmol·mmol−1 creatinine. The prevalences of abnormal values did not differ from those observed in the reference group. No correlation was found between the concentrations of chromium or nickel in urine and that of proteins or enzymes. No consistent or clinically significant renal impairment was revealed among the stainless steel welders exposed to a chromium air concentration slightly above the current threshold limit value of the American Conference of Governmental Industrial Hygienists for water-soluble hexavalent chromium compounds (50 µg·m−3).

Key terms: chromium, enzymes, nephrotoxicity, nickel, proteins, welders.

Hexavalent (VI) chromium can produce acute renal tubular effects in humans or animals. Depending on the dose, these effects can vary from slight tubular proteinuria to acute tubular necrosis and renal failure. Other signs of tubular toxicity induced by chromium salts include enzymuria, aminoaciduria, and histuria (1).

The question of whether chronic exposure to soluble chromium compounds can induce nephrotoxic effects is still controversial. Epidemiologic studies carried out so far have not consistently suggested an adverse effect on renal function (2—10).

The present study was conducted on a group of stainless steel welders who had been exposed to chromium-containing fumes for 18 years on the average. These workers were also exposed to low concentrations of nickel, a metal which might also exert some effects on the kidney (11). A battery of sensitive markers of nephrotoxicity has been applied to these workers and their referents in order to determine whether long-term exposure to chromium or nickel in welding operations represents, as suggested by some studies (2, 4, 7), a significant risk to renal function.

Subjects and methods

The group of exposed subjects consisted of stainless steel welders (all male) working in a machine producing factory. These welders carried out manual metal arc welding of chromium-nickel alloyed steel using coated electrodes (MMA/SS). Their work conditions had always remained identical. Fifty-one age-matched men performing only administrative tasks in the same plant were used as referents.

All of the participants were asked to answer a self-administered questionnaire which provided information on occupational, demographic, and health history. Workers suffering from, or having suffered from, a renal or urological disease or any affection likely to compromise the renal function (eg, diabetes, gout) were excluded from the study.

The exposure at workplaces representative of the various activities was assessed from measurements of the airborne concentration of chromium and nickel with a personal sampler. The filter holder was placed inside the welder's face mask. The welding fumes were aspirated with a battery-operated pump at a flow rate of 1.5 l·min−1 and collected on a cellulose nitroester membrane filter (Synpor 4, 36 mm, mean pore size 0.85 µm). The sampling intervals ranged from 3 to 4 h. The filters were ashed with nitric acid and hydrogen peroxide and analyzed for their chromium and nickel content by atomic absorption spectrometry with a Varian AA-175 spectrometer (12).

For both the welders and the referents, the concentration of chromium and nickel was also measured in a spot urine specimen collected after the shift at the end of the workweek. The urinary chromium and

nickel concentrations were determined by atomic absorption spectrometry with a Varian AA—30 spectrophotometer and a Perkin Elmer 5000 spectrophotometer, respectively. The accuracy of the chromium determination was ascertained by participation in the Interlaboratory Comparison Program of the Centre de Toxicologie du Québec (Centre Hospitalier de l’Université Laval, Québec G1V 4G2).

At the time of the study, the values obtained on nine urine samples with chromium concentrations between 50 and 500 nmol · l⁻¹ were on the average 100.7 (SD 8.6)% of the target value. For both chromium and nickel our laboratory participates also in the definition of reference materials from Behringwerke AG Diagnostica (Marburg 1, PO BOX 1140, D—3550 Germany). The values of chromium obtained at the time of the present survey were on the average 113 and 98.6% of the target value for chromium and nickel, respectively.

For the enzyme and protein determination, four spot urine samples were obtained from each subject on the first and last day of a typical workweek, each time upon arrival and at the end of the shift. All of the samples were collected over phosphate buffer pH 7.4 containing sodium azide as a preservative. They were stored at 4°C until the analysis. The concentrations of retinol-binding protein, protein 1, and transferrin in urine were determined by an automated latex agglutination assay (13—15). The concentrations of beta-microglobulin and albumin were determined by the RIM test (UVVVR Prague, Czechoslovakia). Urinary creatinine was determined by the alkaline picate method (Autoanalyser Technicon). The urinary activity of lysozyme and that of beta-N-acetylglucosaminidase were measured by the methods of Litwack (16) and Tucker et al (17), respectively. Lactate dehydrogenase in urine was assayed by the UV-test (Sevac, Czechoslovakia). Total proteins were determined by the BIO-LA Test (Lachema, Czechoslovakia). All of the urinary parameters were corrected for their creatinine content. The results of the analyses performed on urine samples with a creatinine concentration lower than 0.045 mmol · l⁻¹ (0.4 g · l⁻¹) were discarded.

The Kolmogorov-Smirnov test was used to ensure that the variables were normally distributed on an arithmetic or log scale. The homogeneity of variances was checked by the F-test. Student’s t-test was used to compare arithmetic or geometric means. The comparison of prevalences of elevated values was performed with the 2 × 2 chi-square test (with Yates’ correction) using as cutoff values the geometric means plus two geometric standard deviations of the results of the reference group. The level of significance was taken as P<0.05.

Results

The characteristics of the welders and their referents are summarized in table 1. The groups were well matched with respect to age, smoking habits, alcohol, and analgesics consumption. None of the subjects reported a regular use of solvents at home.

The mean concentration of chromium in air was slightly above the threshold limit value (TLV) of the American Conference of Governmental Industrial Hygienists (50 μg · m⁻³ for water-soluble chromium VI compounds), whereas that for nickel was around 50% of the TLV (50 μg · m⁻³ for nickel-soluble compounds). Fifty percent of the individual values of chromium in air exceeded the TLV. The welders’ mean uri-

* Higher than the geometric mean ± 2 geometric SD of the reference values.
· The prevalences were calculated on the basis of the mean of the four measurements.
· P<0.05, chi-square test with Yates' correction.

The urinary concentrations of chromium and nickel were respectively 10 and 2 times above that of the referents (table 1). The urinary excretion of proteins and enzymes in the referents and exposed subjects is compared in table 2. For that comparison, the arithmetic mean of the four urinary analyses performed on each subject was calculated. No statistically significant difference was found in the urinary excretion of total proteins, albumin, beta₂-microglobulin, protein 1, transferrin, retinol-binding protein, lactate dehydrogenase, lysozyme, and beta-N-acetylglucosaminidase.

All of these parameters were also compared in the samples collected upon arrival at work or at the end of the workshift, on both the first and last day of the week. No statistically significant difference emerged from these separate comparisons (results not shown except those at the end of the last workday, which are presented in table 2).

Table 2 also shows the values of the renal parameters in the group of exposed workers with a urinary excretion of chromium higher than 64.5 nmol · mmol⁻¹ creatinine. The only marker to show a statistically significant difference was beta₂-microglobulin. The concentrations of urinary albumin and transferrin were also slightly higher, but the differences from the values of the reference group did not reach the level of statistical significance.

Table 3 presents the results of the same parameters in terms of the prevalences of increased values (as defined in the Subjects and Methods section). A statistical difference was found only for albuminuria at the end of the last workday. We did not find any significant correlation between the urinary concentrations of chromium or nickel and that of the biochemical parameters.

Discussion

The manual metal arc welding of stainless steel carried out by these workers is the welding technique that generates the highest fume concentrations of soluble chromium (as high as 1000 µg · m⁻³). Seventy to ninety percent of chromium in this type of welding fume is present as soluble chromium VI (ie, in a form that can readily cross cellular membranes of the respiratory tract and other organs, particularly the kidney). Nickel, by contrast, is much less abundant in these fumes. This difference is reflected by the results of the air and biological monitoring. The average concentration of nickel in air was below the TLV and the urinary nickel values did not deviate much from what is usually considered the upper limit of normal (9.5 nmol · mmol⁻¹ creatinine)(20). Exposure to soluble chromium was more important since 50% of the individual air analyses exceeded the TLV and
17% of the urinary chromium values were above the tentative maximum permissible level of 64.5 nmol·mmol⁻¹ creatinine (20).

The application of a battery of sensitive markers did not reveal any significant renal abnormality in these workers. No significant effect could be evidenced in the urinary excretion of albumin and transferrin, which are presently the most sensitive indices of glomerular barrier dysfunction. At the end of the last workday, the exposed workers showed a significantly higher prevalence of elevated albuminuria, but this effect was not corroborated by the assay of transferrin. The urinary excretion of enzymes and low-molecular weight proteins was also unchanged, indicating the absence of any subclinical tubular injury or dysfunction. A slight increase in beta₂-microglobulinuria was observed in workers with a urinary chromium level higher than 64.5 nmol·mmol⁻¹ creatinine, but it is unlikely that this effect resulted from significant proximal tubular impairment since the urinary excretion of other low-molecular weight proteins was normal.

In agreement with the present observations a few previous studies (5, 6, 8, 9) have also failed to evidence consistent renal effects in workers exposed to chromium. In particular, Saner et al (6) and Littorin et al (5) reported no increase in the urinary excretion of beta₂-microglobulin in workers with mean concentrations of chromium in urine of 12 and 13.1 nmol·mmol⁻¹ creatinine, respectively. In fact, the beta₂-microglobulin excretion in these two studies was found to be decreased in the exposed workers. Verschoor et al (10) and Zschiesche et al (8) examined workers with a lower exposure to chromium (mean urinary chromium < 10.8 nmol·mmol⁻¹ creatinine) and also found no indication of a renal effect.

By contrast, on the basis of beta₂-microglobulin excretion, Lindberg & Vesterberg (4) have suggested that a slight proximal tubular dysfunction may occur in chromium-exposed workers. The effect reported by these authors was however of marginal statistical significance (P = 0.045) and even questionable since it was based on the application of one-tailed tests. These authors made the assumption that beta₂-microglobulinuria can only be increased, which is contradicted by studies of Saner et al (6) and Littorin et al (5). The exposure levels were low (between 2 and 20 μg chromium·m⁻³), but nevertheless a dose-response relationship was observed between the concentration of chromium in air and the prevalence of elevated beta₂-microglobulin in urine.

In Italy Franchini, Mutti and their co-workers (2, 3, 7, 9) conducted a series of cross-sectional studies on workers exposed to chromium in welding or chrome-plating operations or during the production of chromate salts. They found some evidence of tubular dysfunction or damage on the basis of urinary excretion of total protein, beta-glucuronidase, retinol-binding protein and the antigen Brush border 50. They even found dose-effect or dose-response relationships between the urinary excretion of chromium and that of retinol-binding protein and of the antigen Brush border 50 (9). Most of the abnormal values were observed in subjects with a urinary excretion of chromium higher than 32.3 nmol·mmol⁻¹ creatinine (ie, 15 μg·g⁻¹ creatinine), but above that threshold the degree of tubular impairment was no longer related to the urinary excretion of chromium. Franchini & Mutti (9) explained this phenomenon by postulating that tubular damage observed in chromium-exposed workers is transient and due mainly to acute exposures and that workers become progressively resistant to the effects of more severe or prolonged exposure. However, the failure in the present study to demonstrate any significant renal effects in workers excreting, on the average, 38.7 nmol chromium·mmol⁻¹ creatinine and with a mean duration of exposure of 18 years indicates that, if soluble chromium VI compounds can produce renal changes in occupationally exposed subjects, it is unlikely that these effects occur in workers excreting less than 64.5 nmol chromium·mmol⁻¹ creatinine (ie, 30 μg·g⁻¹ creatinine), which corresponds to the current TLV of hexavalent chromium in air (20).
