A quantum impurity attached to an interacting quantum wire gives rise to an array of new phenomena. Using Bethe Ansatz we solve exactly models describing two geometries of a quantum dot coupled to an interacting quantum wire: a quantum dot that (i) side-coupled and (ii) embedded in a Luttinger liquid. We find the eigenstates and determine the spectrum through the Bethe Ansatz equations. Using this we derive exact expressions for the ground state dot occupation. The thermodynamics are then studied using the thermodynamics Bethe Ansatz equations. It is shown that at low energies the dot becomes fully hybridized and acts as a backscattering impurity or tunnel junction depending on the geometry and furthermore that the two geometries are related by changing the sign of the interactions. Although remaining strongly coupled for all values of the interaction in the wire, there exists competition between the tunneling and backscattering leading to a suppression or enhancement of the dot occupation depending on the sign of the bulk interactions.

I. INTRODUCTION

Coupling a quantum impurity to an interacting one dimensional lead produces some of the most striking phenomena of low dimensional physics. A simple backscattering impurity is known to cause the wire to be split if the interactions are repulsive while a junction between two leads can lead to perfect conductance in the presence of attractive interactions. More interesting still are scenarios in which the impurity has internal degrees of freedom. These allow for richer and more exotic phases to appear. Among these, systems of quantum dots coupled to interacting leads have attracted much attention. The low energy description of the leads is typically given by Luttinger liquid theory which is the effective low energy description of a large number of interacting systems. Here the individual electrons are dissolved and the excitations are bosonic density modes. In contrast, the relevant degrees of freedom on the dot are electronic. A competition ensues between the tunneling from lead to dot which is carried out by electrons and the energy cost of reconstituting an electron from the bosons in the lead.

Such systems are readily achievable in many experimental settings allowing for confrontation of theory with experiment. Luttinger liquids provide the effective description of carbon nano tubes, fractional quantum Hall edges, cold atomic gases, or flowing through nano pores. Additionally they are known to describe tunneling processes in higher dimensional resistive leads and more generally are the archetype of a non-Fermi liquid. Luttinger liquid-quantum dot systems have successfully been realized in a number of experiments. These realize the embedded geometry, see Fig. 1(a) of a dot placed between two otherwise disconnected leads. Measurement of the conductance has revealed interesting non-Fermi liquid scaling as well as Majorana physics.

Building on the work of we use Bethe Ansatz to solve exactly Luttinger liquid-quantum dot systems in both the embedded (see Fig 1(a)) and side coupled (see Fig 1(b)) geometries. The exact solution shows that the spectra of the two geometries are related by changing the sign of the bulk interaction, a fact previously known through bosonization and are described in terms of charge and chiral degrees of freedom. At low energies we show that the dot becomes fully hybridized and acts as a backscattering impurity for the side-coupled model and as a tunnel junction for the embedded system. This creates a competition between the charge and chiral degrees of freedom when the back scattering or tunnel junction is irrelevant, leading to non Fermi liquid exponents in the ground state dot occupation. We then go on to study the finite temperature properties of the system deriving the Thermodynamic Bethe Ansatz equations and using this to obtain the finite temperature dot occupation.

This paper is organised as follows: in section II we introduce the Hamiltonians and construct their exact eigenstates. We derive the exact spectrum of both systems through their Bethe Ansatz equations by means of the off diagonal Bethe Ansatz method. In Section III we find the ground state of the system and derive the exact dot occupation. From this we extract the renormalization group picture of the system and find the

FIG. 1: We consider two geometries of Luttinger dot system; (a) embedded and (b) side-coupled. The embedded geometry also includes a Coulomb interaction between the dot and leads. Once unfolded the side-coupled and embedded geometries are the same but with the latter containing non local interactions.
leading relevant and irrelevant operators in section IV. The thermodynamics of the system are studied in section V where we find the free energy contribution from the dot and use it to obtain the dot occupation at finite temperature. In the final section we conclude.

II. MODELS AND EIGENSTATES

The systems we consider consist of a quantum dot attached to an interacting lead, a Luttinger liquid, the attachment being either in the embedded or the side-coupled geometry. The Hamiltonian of a Luttinger liquid is given by,

\[
H_{LL} = -i \int dx (\psi^+_x \partial_x \psi_x - \psi^+_x \partial_x \psi_x) + 4g \int dx \psi^+_x(x) \psi^+_x(x) \psi_x(x) \psi_x(x) - D \psi^+_x(x) \psi^+_x(x) \psi_x(x) \psi_x(x) + 4g \sum_{\sigma=\pm} \int dx \psi^+_x(x) \psi^+_x(-x) \psi_x(x) \psi_x(x) \psi_x(x)
\]

where \(\psi^+_x\) are right and left moving fermions which interact with a point like interaction of strength \(g\). For the side-coupled geometry we have \(x \in [-L/2, L/2]\) while for the embedded geometry we take two Luttinger liquids restricted to \(x \in [-L/2, 0]\) and \(x \in [0, L/2]\). It is convenient to bring the two systems into similar form by unfolding the embedded geometry in the standard way to give,

\[
H^{emb}_{LL} = -i \int dx (\psi^+_x \partial_x \psi_x - \psi^+_x \partial_x \psi_x) + 4g \sum_{\sigma=\pm} \int dx \psi^+_x(x) \psi^+_x(-x) \psi_x(x) \psi_x(x) + 4g \sum_{\sigma=\pm} \int dx \psi^+_x(x) \psi^+_x(-x) \psi_x(x) \psi_x(x)
\]

The embedded system now consists of one branch of left-movers and one branch of right-movers restricted to \(x \in [-L/2, L/2]\) but unlike the side-coupled system where the left and right fermions interact locally with each other, in the embedded system after unfolding the interaction is between particles of the same chirality and is non local. Further, the spectrum being linear a cut-off needs to be imposed to render the energies finite. We shall impose it on the particle momenta: \(k \geq -D\). All physical quantities are taken to be small compared with the cutoff and at the end of the calculation we send \(D \rightarrow \infty\), to obtain universal results.

The quantum dot is modelled by a resonant level with energy \(\epsilon_0\) described by,

\[
H_{dot} = \epsilon_0 d^\dagger d,
\]

coupled to Luttinger liquid via a tunnelling term,

\[
H_t = \frac{t}{2} (\psi^+_x(0) + \psi^+_x(0)) + h.c
\]

which mediates both forward and backscattering in the model, the latter changing left movers to right movers and vice versa. Furthermore in the embedded system we add a Coulomb interaction between the ends of the leads and the dot which is the same strength as the Luttinger interaction,

\[
H_c = gd^\dagger d \sum_{\sigma=\pm} \psi^+_x(0) \psi_x(0).
\]

Both energy scales in the dot Hamiltonian are small compared the the cut-off, \(\epsilon_0, \Gamma \ll D\), where \(\Gamma = t^2\) is the level width.

We shall determine the spectrum and the full set of exact eigenstates of both Hamiltonians, \(H^{sc} = H_{LL} + H_t + H_{dot}\) and \(H^{emb} = H^{emb}_{LL} + H_t + H_{dot} + H_c\), using the Bethe Ansatz approach, and then proceed to the ground state (\(T=0\)) and thermodynamic (\(T>0\)) properties. The Bethe Ansatz method we employ here is distinct from that which has been typically used for quantum impurity models. As the problem contains both forward and back scattering we must formulate it in an in-out basis with the configuration space being partitioned in regions labelled by both the order of the particles and by their closeness to the origin. The large degeneracy present in the bulk system due to the linear derivative is then used to find a consistent set of wave functions. We illustrate this by explicitly constructing the one and two particle eigenstates from which we can determine the \(N\)-particle states.

After the unfolding procedure the two systems differ only in the two particle interaction meaning the single particle eigenstates are the same in both models. The tunnelling to and from the dot takes place at the origin hence we may expand the wavefunction in plane waves on either side of it, the most general form for the single particle state of energy \(E = k\) being,

\[
\sum_{\sigma=\pm} \int e^{i \kappa x} \left[ \theta(-x) A^{[10]}_\sigma + \theta(x) A^{[01]}_\sigma \right] \psi^+_x(x) |0\rangle
+ Bd^\dagger |0\rangle,
\]

where \(\theta(\pm x)\) are Heaviside functions. The amplitudes \(A^{[10]}_\sigma\) and \(A^{[01]}_\sigma\) are those of an incoming particle and are
related to the outgoing amplitudes $A_{\pm}^{[10]}$ and $A_{\pm}^{[01]}$ (see Fig. 2(a)) by the bare single particle S-matrix $\hat{S}$, which takes an incoming particle to an outgoing one. Trading in the particle momentum $k$ for the rapidity variable $z$, defined as $k - \epsilon_0 = D e^{z/2}$, we have,

$$
\begin{pmatrix}
A_{+}^{[01]} \\
A_{-}^{[10]}
\end{pmatrix} = S(z) \begin{pmatrix}
A_{+}^{[10]} \\
A_{-}^{[01]}
\end{pmatrix} \tag{7}
$$

$$
S(z) = \begin{pmatrix}
\frac{e^{z/2}}{e^{z/2} + i e^z} & \frac{-i e^{z/2}}{e^{z/2} + i e^z} \\
\frac{-i e^{z/2}}{e^{z/2} + i e^z} & \frac{e^{z/2}}{e^{z/2} + i e^z}
\end{pmatrix} \tag{8}
$$

with $e^z = \Gamma/D$. In addition the dot amplitude $B$ is

$$
B = \sum_{\sigma = \pm} \frac{1}{2} e^{(c-z)/2} \begin{pmatrix}
A_{\sigma}^{[10]} + A_{\sigma}^{[01]}
\end{pmatrix}. \tag{9}
$$

From here periodic boundary conditions can be imposed $\psi_+(-L/2) = \psi_+(L/2)$ resulting in

$$
e^{-i De^{z/2}L - ie_0L} \begin{pmatrix}
A_{+}^{[10]} \\
A_{-}^{[01]}
\end{pmatrix} = S(z) \begin{pmatrix}
A_{+}^{[10]} \\
A_{-}^{[01]}
\end{pmatrix} \tag{10}
$$

which can then be solved for the allowed values of the rapidity $z$.

We now proceed to the two particle case wherein the bulk interaction $g$ enters differently in both models. We shall first consider the side-coupled model and discuss the embedded model subsequently. Since the two particle interaction is point-like as is the tunnelling to the dot we may divide configuration space into regions such that the interactions only occur at the boundary between two regions. Therefore away from these boundaries we write the wavefunction as a sum over plane waves. For two particles we require 8 regions which are specified not only by the ordering of the particle positions $x_1$, $x_2$ and the impurity but also according to which position is closer to the origin. For example if $x_1$ is to the left of the impurity, $x_2$ to its right with $x_2$ closer to the impurity then the amplitude in this region is denoted $A_{12}^{[01]}$; $\sigma_j = \pm$ being the chirality of the particle at $x_j$. The region in which $x_1$ is closer is denoted $A_{12}^{[10]}$. The consequence for the wavefunction is that we include Heaviside functions $\theta(xQ)$ which have support only in the region $Q$, e.g. $\theta(x_{[02]}Q) = \theta(x_2)\theta(-x_1)\theta(-x_1 - x_2)$ and $\theta(x_{[12]}Q) = \theta(x_2)\theta(-x_1)\theta(x_1 + x_2)$. The most general two particle state with energy $E = k_1 + k_2 = \sum_{Q=1}^2 De^{z/2} + 2\epsilon_0$ is therefore

$$
|E\rangle = \sum_{Q} \sum_{\sigma_1, \sigma_2 = \pm} \int \theta(xQ) A_{\sigma_1, \sigma_2}^{[Q]} \prod_{j} e^{i\sigma_j k_j x_j} \psi_{\sigma_j}^\dagger(x_j) \langle 0 | 0 \rangle + \sum_{\sigma = \pm} \int \left[ \theta(-x) B_{\sigma}^{[10]} + \theta(x) B_{\sigma}^{[01]} \right] \psi_{\sigma_j}^\dagger(x) d^j | 0 \rangle \tag{11}
$$

The amplitudes $A_{\sigma_1, \sigma_2}^{[Q]}$ are related to each other by S-matrices which are fixed by the Hamiltonian and in turn fix $B_{\pm}^{[10]}$ and $B_{\pm}^{[01]}$. To define these S-matrices we form column vectors of the amplitudes,

$$
\begin{pmatrix}
\bar{A}_1 \\
\bar{A}_2 \\
\bar{A}_3 \\
\bar{A}_4 \\
\bar{A}_5 \\
\bar{A}_6 \\
\bar{A}_7 \\
\bar{A}_8
\end{pmatrix} = \begin{pmatrix}
A_{+}^{[10]} \\
A_{-}^{[10]} \\
A_{+}^{[01]} \\
A_{-}^{[01]} \\
A_{+}^{[210]} \\
A_{-}^{[210]} \\
A_{+}^{[120]} \\
A_{-}^{[120]}
\end{pmatrix} \tag{12}
$$

which have the following interpretation: $\bar{A}_1$ ($\bar{A}_2$) are the amplitudes where both particles are incident on the impurity but particle 2 (1) is closer, $\bar{A}_5$ ($\bar{A}_6$) are the amplitudes in which both particles are outgoing with particle 2 (1) closer to the impurity, $\bar{A}_8$ ($\bar{A}_7$) describes particle 2 (1) having scattered off the impurity and is still closer to the impurity than 1 (2) while $\bar{A}_7$ ($\bar{A}_4$) also describes particle 2 (1) having scattered but with 1 (2) is closer. $\bar{A}_1$ and $\bar{A}_8$ are explicitly depicted in Fig. 3. After applying the Hamiltonian to (11) we find that it is an eigenstate provided,

$$
\begin{pmatrix}
\bar{A}_8 \\
\bar{A}_5 \\
\bar{A}_6 \\
\bar{A}_7
\end{pmatrix} = S_{20}^{[2]} \begin{pmatrix}
\bar{A}_1 \\
\bar{A}_2 \\
\bar{A}_3 \\
\bar{A}_4
\end{pmatrix}, \quad \begin{pmatrix}
\bar{A}_1 \\
\bar{A}_2 \\
\bar{A}_3 \\
\bar{A}_4
\end{pmatrix} = S_{10}^{[1]} \begin{pmatrix}
\bar{A}_5 \\
\bar{A}_6 \\
\bar{A}_7 \\
\bar{A}_8
\end{pmatrix} \tag{13}
$$

$$
\bar{A}_8 = W_{12}^{[20]} \bar{A}_1, \quad \bar{A}_6 = W_{12}^{[10]} \bar{A}_4, \quad \begin{pmatrix}
\bar{A}_1 \\
\bar{A}_2 \\
\bar{A}_3 \\
\bar{A}_4
\end{pmatrix} = S_{12} \begin{pmatrix}
\bar{A}_5 \\
\bar{A}_6 \\
\bar{A}_7 \\
\bar{A}_8
\end{pmatrix} \tag{14}
$$

The S-matrices $S_{20}^{[20]}$ and $S_{10}^{[10]}$ take a particle past the impurity, i.e. from incoming to outgoing are

$$
S_{20}^{[20]} = S(z_2) \otimes 1, \quad S_{10}^{[10]} = 1 \otimes S(z_1), \tag{17}
$$
with \( S(z) \) the same as in the single particle state \( \| \),
the S-matrix \( S^{12} \) scatters an incoming particle past an outgoing particle and is

\[
S^{12} = \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & e^{i\phi} & 0 & 0 \\
0 & 0 & e^{i\phi} & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}.
\]

where \( \phi = -2 \arctan (g) \) encodes the bulk interaction and
\( W^{12}(z_2 - z_1) \) which scatters an incoming (outgoing) particle past another incoming (outgoing) particle is given by

\[
W^{12}(z) = \begin{pmatrix}
1 & 0 & 0 & 0 \\
0 & \frac{\sinh \frac{1}{2} (z)}{\sinh \frac{1}{2} (z)} & \frac{-i e^{i\phi}}{\sinh \frac{1}{2} (z)} & 0 \\
0 & \frac{i e^{-i\phi}}{\sinh \frac{1}{2} (z)} & \frac{-i e^{i\phi}}{\sinh \frac{1}{2} (z)} & 0 \\
0 & 0 & 0 & 1
\end{pmatrix}.
\]

In addition the dot amplitudes are given by

\[
B^{[10]}_{\pm} = \frac{1}{2} e^{-(z_2)/2} \sum_{\sigma = \pm} \left[ A^{[210A]}_{\sigma \pm} + A^{[201A]}_{\sigma \pm} \right],
\]

\[
B^{[01]}_{\pm} = \frac{1}{2} e^{-(z_2)/2} \sum_{\sigma = \pm} \left[ A^{[120A]}_{\sigma \pm} + A^{[102A]}_{\sigma \pm} \right],
\]

\[
B^{[10]}_{\pm} = \frac{1}{2} e^{-(z_1)/2} \sum_{\sigma = \pm} \left[ A^{[201B]}_{\sigma \pm} + A^{[021B]}_{\sigma \pm} \right].
\]

Inserting these expressions for the amplitudes into \( \| \) we get the two particle eigenstate of the side-coupled model. Since all amplitudes are generated from \( \bar{A}_j \) by successive application of the various S-matrices, as depicted in Fig. 4, there are two ways to obtain each \( \bar{A}_j \) both of which must be equivalent for the construction to be consistent. This consistency imposes that the S-matrices satisfy a generalised Yang Baxter equation which takes the form of the reflection equation

\[
S^{20}S^{12}S^{10}W^{12} = W^{12}S^{10}S^{12}S^{20}
\]

which can be checked to hold by substitution.

It is important to note that while no interaction between two incoming (outgoing) particles is present in the Hamiltonian, \( W^{12} \) is introduced in order to obtain the correct eigenstates and satisfy the generalised Yang-Baxter consistency conditions. To do so we exploit the freedom to introduce discontinuities of the form \( \theta(\pm (x_1 - x_2)) \) into the the part of the wave function that describes two right movers or two left movers (or \( \theta(\pm (x_1 + x_2)) \) into the the part of the wave function that describes one left mover and one right mover). The kinetic term in the Hamiltonian referring to these particles is of the form \( \pm i(\partial x_1 + i\partial x_2) \) (or \( \pm i(\partial x_1 - i\partial x_2) \)) and vanishes when acting on these discontinuities. This freedom arises from the linear spectrum that brings about an infinite degeneracy of the energy levels, the level \( k_1 + k_2 \) being degenerate with \( (k_1 + q) + (k_2 - q) \) for any \( q \). The introduction of the discontinuities corresponds then to the correct choice of basis states in this degenerate subspace from which the perturbation can be turned on, as we are instructed to do carrying out perturbation theory from a degenerate level. For more detail see [13].

We can then go on to impose periodic boundary conditions giving

\[
e^{-ik_1 L} \bar{A}_1 = S^{12}S^{10}W^{12} \bar{A}_1
\]

\[
e^{-ik_2 L} W^{12} \bar{A}_1 = S^{12}S^{20} \bar{A}_1
\]

which can be solved to determine \( z_{1,2}. \)

The eigenstates for higher particle number are constructed similarly and the \( N \) particle state with energy

\[
E = \sum_{j=1}^{N} k_j = \sum_{j=1}^{N} D e^{x_j/2} + N e_0
\]

is

\[
| E \rangle = \sum_{Q} \sum_{\sigma} \int \theta(x_Q) A_{Q}^{\sigma} \prod_{j=1}^{N} e^{i \sigma_j k_j x_j} \psi^{\dagger}_{\sigma_j} (x_j) | 0 \rangle
\]

\[
+ \sum_{P} \sum_{\sigma} \int \theta(x_P) B_{P}^{\sigma} \prod_{j=1}^{N} e^{i \sigma_j k_j x_j} \psi^{\dagger}_{\sigma_j} (x_j) d | 0 \rangle
\]

Here \( \theta(x_Q) \) are Heaviside functions which partition configuration space into \( 2^N N! \) regions. As before \( Q \) are labelled by the ordering of the \( N \) particles as well as according to which particle is closest to the origin while \( \sigma = (\sigma_1, \ldots, \sigma_N) \) with \( \sigma_j = \pm \). In the second line the primed sums indicate that one particle is removed - being on the dot - and the sums are over the remaining
of the same form as \((25)\) but owing to the different bulk interaction in \([2]\) the two particle S-matrices are

\[
S_{ij}^{\text{emb}} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix},\]

(34)

and the single particle S-matrices \(S_{ij}^{0}\) the same as \((26)\). The inclusion of the Coulomb term \((5)\) is essential for this and in its absence the model is not integrable.

Imposing the boundary condition \(\psi_{\pm}(L/2) = e^{i\phi}\psi_{\pm}(L/2)\) we have another eigenvalue problem,

\[
e^{-ik_j L} A_{\sigma_1...\sigma_N} = (Z_j^{\text{emb}})^{\sigma'_1...\sigma'_N}_{\sigma_1...\sigma_N} A_{\sigma'_1...\sigma'_N},\]

(36)

where \(Z_j^{\text{emb}}\) is defined similarly to \(Z_j\) in \((32)\) but using \(W_{ij}^{\text{emb}}\) and \(S_{ij}^{\text{emb}}\) and is related to \(Z_j\) by

\[
Z_j^{\text{emb}} = Z_j |_{\phi \rightarrow -\phi}.
\]

(37)

Therefore, the spectrum of the embedded model is obtained from the side-coupled model by changing the sign of the interaction, \(\phi \rightarrow -\phi\).

We can replace the bare phase shift \(\phi\) by the universal Luttinger liquid parameter \(K\) using\((23)\)

\[
K = \frac{1 + \frac{\phi}{\pi}}{1 - \frac{\phi}{\pi}} \quad \text{side-coupled}
\]

\[
K = \frac{1 + \frac{\phi}{\pi}}{1 - \frac{\phi}{\pi}} \quad \text{embedded}
\]

(38)

meaning that in the thermodynamic limit the two models are related by taking \(K \rightarrow 1/K\) which recovers the duality shown by bosonization\([5]\). In the subsequent sections all calculations will be done for the side-coupled model the results of which can then be translated to the embedded model by taking \(K \rightarrow 1/K\). Note that as \(\phi\) is a phase shift and restricted to \([-\pi, \pi]\) we see that the side-coupled system may realize values of \(K \in [0, 2]\) whereas the embedded system has \(K \in [1/2, \infty]\).

### III. DERIVATION OF THE BETHE ANSATZ EQUATIONS

Our task now is to determine the eigenvalues of \(Z_j\).

To this end we note that \(W^V\) is actually the R-matrix of the XXZ model, and further that \(Z_j\) takes the form of the transfer matrix of an inhomogeneous open XXZ model\([10]\). The problem of diagonalising this operator has recently been achieved by means of the "Off Diagonal Bethe Ansatz"\([11]\). Inserting these results into \((32)\) and

\[
S_{ij}^{0} = S_j(z_j) \otimes_{k \neq j} 1,\]

(26)

\[
S_{ij} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & e^{i\phi} & 0 & 0 \\ 0 & 0 & e^{i\phi} & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad \otimes_{k \neq i, j} 1,\]

(27)

\[
W_{ij} = \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}, \quad \otimes_{k \neq i, j} 1.
\]

(28)

where the subscripts denote which particle spaces the operators act upon. In order for this wavefunction to be consistent it must satisfy the following Yang-Baxter and reflection equations,

\[
S_{ij}^{k} S_{ij}^{0} W_{j}^{k} = W_{j}^{k} S_{ij}^{0} S_{ij}^{k},\]

(29)

\[
W_{j}^{k} W_{j}^{l} W_{j}^{k} = W_{k}^{l} W_{j}^{j} W_{j}^{k},\]

(30)

\[
W_{j}^{k} S_{ij}^{j} S_{ij}^{k} = S_{kl}^{i} S_{ij}^{j} W_{j}^{k}.
\]

(31)

The first of these being the generalisation to \(N\) particles of \((22)\) while the remaining two come from the consistency of the wavefunction away from the dot. These are indeed satisfied by \((25), (27)\) and \((33)\) which is a sufficient condition for the consistency of the wave function\([39]\).

The expressions for \(B_{ij}^{\sigma}\) in terms \(A_{ij}^{\sigma}\) can also be found and are straightforward generalisations of \((23)\) and \((24)\). Therefore we have successfully constructed the \(N\) particle eigenstates of the side-coupled model.

The spectrum can then be determined by imposing periodic boundary conditions \(\psi_{\pm}(L/2) = e^{i\phi}\psi_{\pm}(L/2)\). As we are interested in studying properties of the dot in the thermodynamic limit the type of boundary condition imposed at \(x = \pm L/2\) will not affect the result. This results in an eigenvalue problem which determines the \(k_j\) through

\[
e^{-ik_j L} A_{\sigma_1...\sigma_N} = (Z_j)^{\sigma'_1...\sigma'_N}_{\sigma_1...\sigma_N} A_{\sigma'_1...\sigma'_N},\]

(32)

\[
Z_j = W_{j}^{j-1}...W_{j}^{1} S_{j}^{1}...S_{j}^{N} S_{j}^{0} W_{j}^{j+1}...W_{j}^{L},
\]

(33)

where the matrix \(Z_j\) takes the \(j\)th particle past all others and past the impurity. By using \((22), (30)\) and \((31)\) one can show that the \(Z_j\) commute with each other \([Z_{j}, Z_{k}] = 0 \forall j, k\). They are therefore simultaneously diagonalisable and the spectrum of the side-coupled model is determined by the eigenvalues of the \(Z_j\) operators. Before obtaining these we return to constructing the eigenstates of the embedded model.

For the embedded impurity model we note that the unfolding procedure carried out previously allows us to construct its eigenstates in the same manner as we did for the side-coupled model. The \(N\) particle eigenstate is
simplifying the resulting equations using \(e^c \ll 1\) in the same manner as in \(^{23}\) we obtain the Bethe equations for the side-coupled model

\[
e^{-iDc^{\alpha}/2L} = e^{iN\phi/2+i\phi_0L} \left[ e^{\lambda_0/2 - i\phi} \right]^{1/2} \times \prod_k^{N/2} \frac{\sinh \left( \frac{1}{2} (z_\alpha - \lambda_k - i\phi) \right)}{\sinh \left( \frac{1}{2} (z_\alpha - \lambda_k + i\phi) \right)} \prod_\alpha \frac{\sinh \left( \frac{1}{2} (\lambda_j - z_\alpha + i\phi) \right)}{\sinh \left( \frac{1}{2} (\lambda_j - z_\alpha - i\phi) \right)} = - \left[ \frac{\cosh \left( \frac{1}{2} (\lambda_j - 2c + i\phi) \right)}{\cosh \left( \frac{1}{2} (\lambda_j - 2c - i\phi) \right)} \right]^{1/2} \times \prod_k^{N/2} \frac{\sinh \left( \frac{1}{2} (\lambda_j - \lambda_k + 2i\phi) \right)}{\sinh \left( \frac{1}{2} (\lambda_j - \lambda_k - 2i\phi) \right)}
\]

with each pair having bare energy \(-2 \cos (\phi/2)Dc^{\lambda_j}\), see Fig. 7.

Inserting these expressions into \(^{29}\) and \(^{40}\) we obtain equations for the real parts of the pairs, \(\lambda_j\). In the thermodynamic limit we are not interested in the solutions per se, but in their distribution,

\[
\rho_1(\lambda_j) = \frac{1}{L(\lambda_j - \lambda_{j-1})}
\]

on the real line. The distribution has contributions from the bulk as well as from an \(O(1/L)\) term from the dot, allowing us to write it as \(\rho_1(\lambda) = \rho_1^b(\lambda) + \frac{1}{L}\rho_1^d(\lambda)\). The dot occupation is then given as,

\[
n_d = 2 \int \rho_1^d(\lambda).
\]

The factor of 2 appears here as each \(\lambda\) corresponds to a pair of rapidities. These distributions, \(\rho_1^b(\lambda)\), \(\frac{1}{L}\rho_1^d(\lambda)\) are determined by the Bethe equations in their continuous form which for the bulk part is,

\[
\frac{\cos \phi/2}{2\pi} De^{\lambda/2} = \rho_1^b(\lambda) + \int_{-\infty}^{\infty} a_\mu(\lambda - \mu) \rho_1^b(\mu) \quad (44)
\]

where \(B = B(\epsilon_0)\) is the \(\lambda\) value of the highest filled level. When the dot energy vanishes we have that \(B(0) = \infty\) and bulk distribution is found to be

\[
\rho_1^b(\lambda) = \frac{De^{\lambda/2}}{4\pi \cos(\phi/2)} \quad (46)
\]

with the bulk part of the ground state energy being

\[
E_0 = -\int_{-\infty}^{\infty} 2 \cos (\phi/2)De^{\lambda/2} \rho_1^b(\lambda).
\]

The factor of 2 appears here as each \(\lambda\) corresponds to a pair of rapidities. These distributions, \(\rho_1^b(\lambda)\), \(\frac{1}{L}\rho_1^d(\lambda)\) are determined by the Bethe equations in their continuous form which for the bulk part is,

\[
\frac{\cos \phi/2}{2\pi} De^{\lambda/2} = \rho_1^b(\lambda) + \int_{-\infty}^{\infty} a_\mu(\lambda - \mu) \rho_1^b(\mu) \quad (44)
\]

where \(B = B(\epsilon_0)\) is the \(\lambda\) value of the highest filled level. When the dot energy vanishes we have that \(B(0) = \infty\) and bulk distribution is found to be

\[
\rho_1^b(\lambda) = \frac{De^{\lambda/2}}{4\pi \cos(\phi/2)} \quad (46)
\]

with the bulk part of the ground state energy being

\[
E_0 = -\int_{-\infty}^{\infty} 2 \cos (\phi/2)De^{\lambda/2} \rho_1^b(\lambda).
\]

To confirm this is indeed the ground state one can introduce excitations and check the energy is increased, the simplest type of which consists of adding holes to the distribution. As is typical for Bethe ansatz models, the energy of a hole turns out to be proportional to the ground state distribution i.e. a hole at \(\lambda = \lambda^h\) has energy \(\varepsilon^h(\lambda^h) = 4\pi \rho_1^d(\lambda^h)\), increasing the energy. The other excitations consist of breaking up a pair and placing them above the Fermi surface such that they have real rapidity. Each particle then has energy \(\varepsilon^b(z) = 2De^{\pi/2}\) in addition to the hole introduced in the \(\rho_1(\lambda)\) distribution.

When \(\epsilon_0 \neq 0\) the additional term in the energy (see \(^{41}\)) needs to be balanced by the addition of holes to the ground state with rapidities starting at \(-B(\epsilon_0)\). The form of the hole energy, \(\varepsilon^h(\lambda)\) gives us that

\[
B(\epsilon_0) = \log \left( \frac{\alpha D}{\epsilon_0} \right) \quad (48)
\]
where \( \alpha \) is a constant.

Considering now the dot part of the Bethe equations, the dot contribution to the density satisfies,

\[
f_1(\lambda - 2c) = \rho_1^d(\lambda) + \int_B a_2(\lambda - \mu)\rho_1^d(\mu), \quad (49)
\]

with

\[
f_n(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} e^{iwx} \frac{\sinh(\pi - n\phi)\omega}{\sinh 2\pi \omega}, \quad (50)
\]

The solution is obtained by the Wiener-Hopf method (see 
\([13,16,19,20]\) and references therein). Upon integrating over the result as in \([13]\) we find that the exact dot occupation in the ground state is,

\[
n_d = -i 2\pi \int_{-\infty}^{\infty} d\omega e^{-i\omega(2\log(\pi^2/4) + a)} \sinh(2\pi \omega) \Gamma\left(\frac{1}{2} + i(K - 1)\omega\right)
\]

where \( \Gamma(x) \) is the Gamma function, \( a \) is a non-universal constant and we have used \([58]\) to write \( n_d \) in terms of the Luttinger \( K \). As there is no dependence on the cutoff we can safely take the universal limit \( D \to \infty \) while holding the level width \( \Gamma \) fixed. The width serves as both the coupling constant and as the strong coupling scale for \( \rho_1^d(\lambda) \) being hybridized and having \( \epsilon_0/G \) as a constant.

The ground state takes a different form in the region \( \phi \in [-\pi, 0] \) which corresponds to \( K \in [0,1] \). It is constructed by taking the chiral parameters \( \lambda_j \in \mathbb{R} \) to be real and the rapidities placed on the \( 2\pi i \) line i.e. \( \text{Im}(z_\lambda) = 2\pi \). Inserting these values into the Bethe equations and then passing to the continuous form we obtain a set of coupled integral equations for the distributions of the charge, \( \rho_{-}(z_j) = 1/L(z_j - z_{j-1}) \) and chiral variables \( \sigma_1(\lambda_j) = 1/L(\lambda_j - \lambda_{j-1}) \) which we can again split into bulk and dot contributions. The bulk contributions \( \rho^b_\lambda(z) \) and \( \sigma_1^b(\lambda) \) are governed by the continuous Bethe equations,

\[
\begin{align*}
\rho^b_\lambda(z) &= \rho^b_\lambda(y) - \int_{-B'} \rho_{-}^b(z-y)\sigma_1^b(y) \\
\sigma_1^b(\lambda) &= \sigma_1^b(\lambda - y) + \int_{-\infty}^{\infty} \rho_{-}^b(\lambda - y)\sigma_1^b(y)
\end{align*}
\]

where the rapidities are bounded by \( -B'(\epsilon_0) \). When the dot energy is set to zero we have that \( B'(0) = \infty \) and the bulk ground state distributions are found to be,

\[
\begin{align*}
\rho^b_\lambda(z) &= \frac{D_{e^{2z/4\pi}}} {2\pi}, \\
\sigma_1^b(\lambda) &= \frac{D_{e^{2z/4\pi}}}{4\pi \cos(\phi/2)}
\end{align*}
\]
In the previous section we derived exact expressions for the dot occupation for the side-coupled model as function of $\phi_0$ measured with respect to the strong coupling limit. The dot occupation for the embedded system is simply obtained from (51) by using the mapping $K \rightarrow 1/K$.

The solution is again determined by the Viener-Hopf integral

$$\phi_0 = \int 2\pi \sigma \left\{ \frac{\sin(\pi/2)}{\sin(\pi/4)} \right\} d\omega$$

The corresponding expression for the strong coupling scale is

$$\Gamma = \frac{\sqrt{2}}{\pi} \frac{\sin(\pi/2)}{\sin(\pi/4)} \int 2\pi \sigma \left\{ \frac{\sin(\pi/2)}{\sin(\pi/4)} \right\} d\omega$$

We now have the following picture of the side-coupled model.

1. The single lead case: $K = 1$, the system is described by a Luttinger liquid with free fermions at the edge. The tunnelling operator $\phi_0$ is fully hybridized with the bulk and the fixed point is the stress energy tensor $\phi_0 = 1/2$. The critical scale is given by $\Gamma = \frac{8}{\pi} \sin(\pi/2)$.

2. For $K > 1$, the system is described by a Luttinger liquid with free fermions at the edge. The tunnelling operator $\phi_0$ is fully hybridized with the bulk and the fixed point is the stress energy tensor $\phi_0 = 1/2$. The critical scale is given by $\Gamma = \frac{8}{\pi} \sin(\pi/2)$.

3. For $K < 1$, the system is described by a Luttinger liquid with free fermions at the edge. The tunnelling operator $\phi_0$ is fully hybridized with the bulk and the fixed point is the stress energy tensor $\phi_0 = 1/2$. The critical scale is given by $\Gamma = \frac{8}{\pi} \sin(\pi/2)$.

The fundamental excitations above this ground state consist of adding holes to either of these distributions. The energy of these are $\epsilon (x) = \pi U \delta (x)$ and $\epsilon (x) = 4\pi^2 \delta (x)$.

As in the previous section, the dot occupation is determined by

$$\phi_0 = \frac{1}{2} \int 2\pi \sigma \left\{ \frac{\sin(\pi/2)}{\sin(\pi/4)} \right\} d\omega$$

The energy of these are also given by (51). Note however that the poles at $K < 1$ modify the expansion about these points, however the leading term is still given by $\rho (\omega) = 1$.

The fundamental excitations above this ground state consist of adding holes to either of these distributions. The energy of these are $\epsilon (x) = \pi U \delta (x)$ and $\epsilon (x) = 4\pi^2 \delta (x)$.

As in the previous section, the dot occupation is determined by

$$\phi_0 = \frac{1}{2} \int 2\pi \sigma \left\{ \frac{\sin(\pi/2)}{\sin(\pi/4)} \right\} d\omega$$

The energy of these are also given by (51). Note however that the poles at $K < 1$ modify the expansion about these points, however the leading term is still given by $\rho (\omega) = 1$.
relevant and generates no other terms in the expansion. The high energy fixed point describes a decoupled dot which has \( n_d = 0 \) for \( \epsilon_0 \rightarrow \infty \) or \( n_d = 1 \) for \( \epsilon_0 \rightarrow -\infty \). By reducing the energy scale we flow away from the fixed point with the tunnelling operator \( d^\dagger \psi_{\pm} (0) \) which is the leading relevant operator and has dimension \( 1/2 \) as in the free model. This give rise to integer powers of \( \Gamma/\epsilon_0 \) in \( n_d \). Additionally when \( K < 1 \) backscattering is relevant and causes odd powers of \( (\Gamma/\epsilon_0)^{1/(1-K)} \) to appear resulting in an enhancement of the dot occupation.

VI. THERMODYNAMICS

A. \( K = \frac{\nu - 1}{\nu} \)

In this section we study the finite temperature properties of the dot by calculating the free energy. To do so we use the methods developed by Yang and Yang and later extended by Takahashi based on the string hypothesis. This states that in the thermodynamic limit the solutions of the Bethe equations take complex values organised into strings. The form of the strings depend upon the model and the values of the parameters therein. To simplify matters we take \( \phi = \pm \pi/\nu \) with \( \nu \) an integer so that \( K = \frac{\nu - 1}{\nu} \). With this value fixed the hypothesis states that the Bethe equations allow for the following forms of the charge and chiral variables.

The rapidities can be real or complex with \( \text{Im}(z) = 0, 2\pi \). These contribute bare energy \( \pm D e^{\nu/2} \) and we denote the distributions of these \( \rho_\pm (z) \). The chiral variables can take on complex values so that they arrange into \( n \)-strings with \( n < \nu \) such that

\[
\lambda^{(n)}_l = \lambda^{(n)} + i\phi(n - 1 - 2l), \quad l = 0, \ldots, n - 1
\]  

or \( \lambda \) on the \( i\pi \) line which is sometimes called a negative parity string. The \( \lambda \) \( n \)-strings have no bare energy and we denote the distributions of their real part, called the string centre \( \sigma_n(\lambda) \) with \( n = \nu \) denoting the negative parity string. Also possible are \( z-\lambda \) \( 2n \)-strings consisting of \( 2n \) \( z \)s and a \( \lambda \) \( n \)-string taking the values

\[
\begin{align*}
\lambda^{(n)}_{l+1} &= \lambda^{(n)} + i\phi(n - 2l) + i\pi + \text{sgn}(\phi)i\pi \\
\lambda^{(n)}_{l+n+1} &= \lambda^{(n)} + i\phi(n - 2l) + i\pi - \text{sgn}(\phi)i\pi
\end{align*}
\]  

where \( j = 0, \ldots, n \) and \( l = 1, \ldots, n - 1 \). These contribute bare energy \( E_n = -2\text{sgn}(\phi) \cos(\phi/2)D e^{\nu/2} \). In addition there is also a negative parity \( z - \lambda \) string

\[
\lambda = \lambda^{(\nu)} + i\pi, \quad z_{1,2} = \lambda^{(\nu)} \pm i(\pi - \phi)
\]

which has energy \( 2\sin(\phi/2)D e^{\nu/2} \). We denote the distributions of the centres of the \( z - \lambda \) \( 2n \)-strings by \( \rho_n(z) \) with \( n = \nu \) indicating the negative parity string. Several string type are depicted in Fig. 7 for both \( \phi > 0 \) and \( \phi < 0 \).

Having elucidated the string structure of the model, the free energy is found, as in other Bethe ansatz models following the procedure laid out in. The approach is well known and we just provide the main steps. The free energy \( F = E - TS \), where \( E \) is the energy of an arbitrary configuration of strings and \( S \) is its associated Yang-Yang entropy, is minimized with respect to \( \rho_\pm, \rho_\nu \) and \( \sigma_n \) which are solutions of the Bethe Ansatz equations. The result of this minimization gives the thermodynamic Bethe ansatz (TBA) equations which determine the minimum of \( F \). Owing to the different string structures for \( K \) greater than or less than \( 1 \) we consider each region separately.

We start with \( \phi = -\pi/\nu \), corresponding to \( K = \frac{\nu - 1}{\nu} \), describing repulsive interactions. In this region we find
the effect most pronounced as the temperature is lowered.

\[ F_d = E_d^0 - T \int f_0(x + 2 \log \left(\frac{T}{\Gamma}\right)) \log (1 + e^{\phi - (x)}) \]

\[ -T \int f_0 * s(x + 2 \log \left(\frac{T}{\Gamma}\right)) \log (1 + e^{\phi_1(x)}) \]

\[ -T \int s(x + 2 \log \left(\frac{T}{\Gamma}\right)) \log (1 + e^{\phi_{\nu-1}(x)}) \quad (65) \]

where \( E_d^0 \) is the ground state energy due to the dot, \( s(x) = \text{sech}(\pi x/2\phi)/4\phi \) and * denotes the convolution \( f * g = \int f(x - y)g(y)dy \). The thermodynamic functions \( \phi_\pm, \phi_n \) and \( \nu_n \) are related to the distributions \( \rho_\pm, \rho_n \) and \( \sigma_n \) respectively and are solutions of the TBA equations which in this case are

\[
\phi_+ = s \log \left(\frac{1 + e^{\phi_1}}{1 + e^{\nu_1}}\right), \quad \phi_- = -2e^{\phi/2} + s \log \left(\frac{1 + e^{\nu_1}}{1 + e^{\nu_1}}\right) \quad (66)
\]

\[
\phi_n = s \log \left(\frac{1 + e^{\nu_{n-1}}}{1 + e^{\nu_{n+1}}}\right) (1 + e^{-\phi_\nu}) (1 + e^{-\phi_\nu}) \delta_{n,\nu^2} + \delta_{n,1} s \log \left(\frac{1 + e^{\phi_\nu}}{1 + e^{\nu_1}}\right) \quad (67)
\]

\[
\nu_n = s \log \left(\frac{1 + e^{\nu_{n-1}}}{1 + e^{\nu_{n+1}}}\right) ^{1+\delta_{n,\nu^2}} - \delta_{n,1} \left[ \frac{e^{\phi/2} - e^{\nu_1}}{\cos (\phi/2)} - s \log \left(\frac{1 + e^{\phi_\nu}}{1 + e^{\nu_1}}\right) \right] \quad (68)
\]

along with \( \phi_{\nu-1} = s \log \left(\frac{1 + e^{\phi_{\nu-2}} + \nu_0}{1 + e^{\nu_0}}\right) = -\phi_\nu + 2\nu_0 \) and \( \nu_{\nu-1} = s \log \left(\frac{1 + e^{\nu_{\nu-2}}}{1 + e^{\nu_{\nu-2}}}\right) = -\nu_\nu \). Just as in the calculation of the dot occupation in the ground state the above equations are independent of the cutoff which has been removed while holding \( \Gamma \) fixed. These expressions give the exact dot free energy of the system in all temperature regimes. Their complicated nature precludes any analytic solution for the thermodynamic functions but are straightforwardly determined numerically through iteration of the integral equations.

Before doing this however we can examine them in the limits of low and high temperature. The functions \( f_0(x) \) and \( s(x) \) appearing in the free energy are sharply peaked about zero meaning that for \( T \to 0, \infty \) the free energy is determined by the solutions of the TBA in the \( x \to \infty, -\infty \) limits respectively. Setting \( \epsilon_0 = 0 \) and taking first the high temperature limit, \( x \to -\infty \) we see that the driving terms in the TBA vanish and the thermodynamic functions are constants \( e^{\phi_\nu(-\infty)} = 1 \),

\[
e^{\nu_{\nu-1}(-\infty)} = (j + 1)^2 - 1 \quad (69)
\]

\[
e^{\phi_{\nu-1}(-\infty)} = e^{\nu_{\nu-1}(-\infty)} = \nu - 1. \quad (70)
\]

Likewise in the opposite low temperature limit \( x \to \infty \)

we get \( e^{\phi_\nu(\infty)} = 0, \quad e^{\nu_1(\infty)} = 3, \quad e^{\nu_{\nu-1}(\infty)} = \nu - 2 \quad (71) \)

\[
e^{\nu_1(\infty)} = (j + 2)^2 - 1, \quad e^{\nu_{\nu-1}(\infty)} = \nu. \quad (72)
\]

The free energy thus becomes linear in \( T \) in both the high and low temperature limit.

Using these we can check the RG picture we arrived at earlier using the ground state dot occupation still holds true at finite temperature. Firstly note that the energy scale, the temperature in this case, is measured with respect to \( \Gamma \) which serves as both the strong coupling scale and the level width for the model. Thus the system is strongly coupled at low temperature \( T \ll \Gamma \) and weakly coupled at high temperature \( T \gg \Gamma \). Furthermore by inserting (71) into (65) we obtain the \( g \)-function of the model, defined to be the difference in the UV and IR entropy of the impurity

\[
g = S_{UV} - S_{IR} = \log 2 + \frac{1}{2} \log \left(\frac{1}{K}\right). \quad (73)
\]

This is always positive for the range of values considered in agreement with the requirement that as we move along the RG flow by lowering the temperature, massless
degrees of freedom are integrated out. The first term comes from the charge degrees of freedom and corresponds to the entropy of a decoupled dot at high temperature which is fully hybridised at low temperature. The second term comes from the chiral degrees of freedom and is the same as for the Kane-Fisher model of a back scattering impurity. We see from this that at high temperature the dot is decoupled and as $T$ is lowered it becomes hybridised with the dot whereupon it acts as a back scattering impurity. In the non interacting limit the $K \to 1$ this last term disappears and we recover the expected result.

We may go beyond the fixed point behaviour to get the leading order corrections and determine the specific heat. Following[23] we expand about the low temperature solution $\log(1 + \exp(\varphi_-)) \approx \exp(-2e^{\varphi_-}/2)$ and $\log(1 + \exp(\varphi_1)) \approx \exp(-e^{\varphi_1}/\cos(\phi/2))$ for $x \gg 0$. The low temperature specific heat is then found to be

$$C_v \approx \frac{T}{\Gamma}$$

which agrees with the expectation that the irrelevant operator is the stress energy tensor.

By numerically integrating the TBA and using them in[69] we can obtain the finite temperature dot occupation of the system. This is plotted in Fig. 8 for $K = \frac{2}{3}$ as a function of $e_0/\Gamma$ at different values of the temperature, $T/\Gamma$. For the same value of $K$ we plot the dot occupation at fixed $e_0/\Gamma$ as a function $T/\Gamma$ in the Fig. 9. Comparing to the dashed lines which are the non interacting values we see that the dot occupation is enhanced just as it was at zero $T$. This enhancement is strongest at low $T$ and is washed out at high temperature as the system becomes weakly coupled.

**B. $K = \frac{\nu + 1}{\nu}$**

We turn now to the case of $\phi = \pi/\nu$ or $K = \frac{\nu + 1}{\nu} > 1$, (attractive interactions). In this regime the tunneling is relevant while backscattering is irrelevant[70]. A competition therefore ensues between these two processes. This competition makes itself felt via changes in the free energy and TBA equations. The dot contribution to the free energy is now given by

$$F_d = E_d^0 - T \int f_0(x + 2 \log\left(\frac{T}{\Gamma}\right)) \log(1 + e^{-\varphi+(x)}) - T \int f_0 * s(x + 2 \log\left(\frac{T}{\Gamma}\right)) \log(1 + e^{\varphi_1(x)})$$

with the TBA equations being

$$\varphi_+ = 2e^{\varphi_-}/2 + s \log\left(\frac{1 + e^{\varphi_1}}{1 + e^{\varphi_1}}\right), \quad \varphi_- = s \log\left(\frac{1 + e^{\varphi_1}}{1 + e^{\varphi_1}}\right)$$

$$\varphi_n = s \log((1 + e^{\varphi_{n-1}})(1 + e^{\varphi_{n+1}})(1 + e^{-\varphi_{n+1}})\delta_{n,\nu-2} - \delta_{n,1}s \log\left(\frac{1 + e^{-\varphi_+}}{1 + e^{-\varphi_-}}\right)$$

$$\nu_n = s \log((1 + e^{\varphi_{n-1}})(1 + e^{\varphi_{n+1}})1 + \delta_{n,\nu-2} - \delta_{n,1}s \log\left(\frac{1 + e^{-\varphi_+}}{1 + e^{-\varphi_-}}\right)$$

Using these in the $g$ function we obtain the same form as before,

$$g = \log 2 + \frac{1}{2} \log\left(\frac{1}{K}\right).$$

Note however that although $g > 0$, the second term which is due to the backscattering, is negative for $K > 1$. This relative sign between the charge and chiral terms is related to the competition between the tunneling and the backscattering. Upon taking the $K \to 1$ we recover the non interacting result. The low temperature corrections to the fixed point can be obtained as they were in the previous section. This time however the driving terms in the do not appear in the $\varphi_1$ equation but in the $\varphi_1$ equation instead and consequently we take $\log(1 + \exp(-\varphi_+)) \approx \exp(-2e^{\varphi_-}/2)$.
and \( \log (1 + \exp (\varphi_1)) \approx \exp (-e^{\varphi_1} / \cos (\varphi_2)) \) for \( x \gg 0 \) and find the specific heat to be
\[
C_v \sim \frac{T}{\Gamma} + a \left( \frac{T}{\Gamma} \right)^\alpha
\]
Again the leading order term coincides with the stress tensor being the leading irrelevant operator. The term scales as \( T^\alpha \) where \( \alpha = 2 \) for \( K = \frac{\nu+1}{\nu} \), \( \nu > 2 \). It is expected however that \( \alpha \) becomes non integer when increasing \( K \) beyond this as is the case in the ground state dot occupation.

The finite temperature dot occupation can be obtained by numerically integrating the TBA as in the previous section and the results are plotted in Fig. 8 and Fig. 9. We see that the dot occupation is suppressed as compared to \( K = 1 \) or \( K < 1 \), with the effect being most pronounced at low temperature. At high \( T \) the dot becomes decoupled and the occupation approaches that of the non interacting case.

VII. CONCLUSION

In this article we have solved two related models of quantum dots coupled to Luttinger liquids. The first consists of a dot side-coupled to the Luttinger liquid while in the second the dot is placed between two otherwise disconnected liquids. The latter also requires that a Coulomb interaction between the occupied dot and the end of the liquids is included and it is tuned to the same value as the bulk interaction. The side-coupled model however, requires no such tuning.

The solution shows that the two models are related by taking \( K \to 1/K \) which was shown previously through bosonization. We derived the Bethe equations for both models and used them to construct the ground state and derive exact expressions for the dot occupation in all parameter regimes. It was seen that the side-coupled system is strongly coupled at low energies so that the dot becomes fully hybridised with the bulk and acts as a backscattering potential. The effect of the backscattering is to either suppress or enhance the dot occupation depending on the sign of the interactions.

The scaling dimensions of the leading relevant and irrelevant operators about the UV and IR fixed points were found to coincide with that of the free model. The surprising result that the fixed points appear, at least to leading order to be Fermi liquid is in stark contrast to the non-Fermi liquid nature of the bulk system.

We then examined the finite temperature properties of the dot by deriving the Thermodynamic Bethe equations and free energy of the system. It was seen that at low temperature dot is fully hybridised with the bulk and the interactions resulting in a suppression or enhancement of the dot occupation. The effect of the interactions is washed out at high temperature whereupon the dot decouples.

The lack of fine tuned parameters in the side-coupled model make it a good candidate for experimental realizations. Such a system may be created placing a quantum dot near a carbon nanotube, the edge of a quantum Hall sample or a topological insulator. The dot occupation can then be measured by means of a quantum point contact and compared to \( \frac{1}{\nu} \).
