ABSTRACT—We investigated the involvements of sympathetic and nonadrenergic nervous systems in the inhibitory reflex following bronchoconstriction in dogs. Inhalations of a 0.00125% solution of histamine and Ascaris suum antigen (3 mg protein) to the bronchial side induced reflex tracheal constriction following bronchoconstriction. An intra-arterial infusion of 5 μg/min of atropine to the tracheal site changed the reflex tracheal constrictions by histamine and antigen inhalations into tracheal dilatations. The reflex tracheal dilatations were abolished by the combination of intra-arterial propranolol (100 μg) and transections of both the bilateral superior laryngeal nerves and the spinal cord at the C1 level. The reflex tracheal constrictions induced by histamine and antigen inhalations were increased with 100 μg propranolol. Furthermore, the reflex tracheal constrictions were enhanced by the combination of 100 μg propranolol and transection of the spinal cord. These findings indicate that during the constriction of the bronchial smooth muscle, not only a reflex tracheal constriction mechanism but also one of reflex dilatation operates and that the latter reflex response may be mainly mediated by the sympathetic nerves, with partial involvement of the nonadrenergic nerves. This inhibitory reflex may attenuate asthmatic bronchoconstriction.

Several studies have reported the role of the vagal reflex in the airway constriction induced by histamine or antigen inhalations (1–9). Hosokawa et al. (10) showed that the vagal reflex constriction of airways results from some complex effects that may be mediated by several sensory receptors in the airways. Stimulations of pulmonary irritant receptors and C-fiber endings induce a vagal reflex bronchoconstriction (11, 12). By contrast, the activation of stretch receptors by transient inflation of the lungs causes a reflex airway dilatation (10). Bartlett et al. (13) reported that the activity of airway stretch receptor increases during tracheobronchial constriction. Furthermore, Widdicombe and Nadel (14) suggested that airway stretch receptors could moderate the bronchoconstriction induced by stimuli like hypoxia and hypercapnia. However, the efferent pathway of the inhibitory reflex induced by activation of stretch receptors is still unknown.

Cabezas et al. (15) found that stimulation of sympathetic nerves inhibits bronchoconstriction. McCulloch et al. (16) reported the existence of an adrenergic-mediated bronchodilatory reflex mechanism. It has been previously demonstrated that reflex tracheal dilatation caused by lung inflation may be mediated by adrenergic innervation and partly by non-adrenergic innervation (17). In the present study, therefore, to confirm the involvements
of sympathetic and nonadrenergic nerves in the inhibitory reflex following histamine- and antigen-induced bronchoconstrictions, we determined if reflex tracheal dilatation occurs during bronchoconstriction and investigated the intervention of these nerves in the reflex tracheal constriction induced by bronchoconstriction.

MATERIALS AND METHODS

Experiments were performed with a preparation that could be used to evaluate the vagal reflex-induced responses of the airway, as described previously (10). Male mongrel dogs weighing 8−14 kg were lightly anesthetized with an i.m.-injection of ketamine hydrochloride (10 mg/kg). The cervical trachea was transected at about 7 cm caudal to the larynx with the membranous wall left intact. Care was taken not to obstruct the recurrent laryngeal nerves. The membranous wall at the transected site was ligated with a thread to interrupt blood flow passage across the wall. A tracheal cannula was inserted into the caudal side of the transected trachea. The animals were immobilized with decamethonium bromide (initial dose of 0.4 mg/kg, i.v., and supplemental doses of 0.2 mg/kg, i.v., every hour) and ventilated with room air by an artificial respirator (Natsume, KN-50) at a frequency of 20 breaths/min. End-tidal concentrations of CO₂ and O₂ were continuously monitored with an expired gas monitor (San-Ei, 1H21), and they were maintained at optimal ventilation levels of 3.5−4.0% and 16.5−17.5%, respectively, under resting conditions. The left femoral artery was cannulated, and the portion on which surgery was performed was treated with 1% procaine hydrochloride. The systemic arterial blood pressure was measured through the catheter connected with a pressure transducer (Nihon Kohden, MPU-0.5). The heart rate was monitored with the tachometer (Nihon Kohden, RT-5) using the systolic blood pressure as the trigger.

Responses of the bronchial musculature were measured by a modification of the Konzett-Rössler method (18). The lungs were ventilated at a fixed volume of air under a constant pressure (10 cmH₂O), and the ventilation overflow was measured using a pneumotachograph (Nihon Kohden, MFP-1T) as an index of the change in bronchial responses. Responses of the tracheal musculature were measured as changes in the intra-tracheal pressure of an air-filled balloon introduced into the rostral side of the transected trachea using a pressure transducer (Nihon Kohden, LPU-0.1). The initial intraluminal pressure of the balloon was adjusted to 50 mmH₂O. In this preparation, the upper tracheal response was estimated fully as the reflex induced by activation of sensory receptors in the bronchus (10). The bilateral recurrent laryngeal nerves were cut beforehand in all animals so that efferent parasympathetic pathway to the upper trachea is only via the bilateral superior laryngeal nerves.

To administer drugs directly to the upper tracheal site where the reflex-induced tracheal responses were measured, we used the in situ technique for perfusion of the upper trachea, as described previously (19). Two arms of a Y-shape cannula were inserted to the bilateral cranial thyroid arteries, and the arterial blood from the right femoral artery was perfused into the cranial thyroid arteries via a peristaltic pump (Tokyo Rikakikai, MP-1011) at a constant flow. The perfusion rate was adjusted at the beginning of each experiment so that the perfusion pressure was approximately equal to the systemic arterial blood pressure. Just before starting the perfusion, the animal was given heparin sodium (700 units/kg, i.v., and maintained by 300 units/kg/hr, i.v.).

Experiments lasted about four hours at the longest. Throughout each experiment, the corneal reflex had disappeared, and systemic blood pressure, heart rate and CO₂ and O₂ levels in expired gas were almost stable under resting conditions.

Drugs used were histamine dihydrochloride (Wako Pure Chemicals), propranolol hydrochloride (Inderal, Sumitomo Chemical Indus-
try) and atropine sulfate (Tokyo Kasei). All
doses were expressed in terms of the base. All
drugs were dissolved or diluted in saline solu-
tion, and they were close-intra-arterially in-
jected into the rubber tubing just before the
Y-shaped cannula.

*Ascaris suum* antigen was prepared with
veronal-buffered saline according to the pre-
vious report (7). In the experiment of antigen
inhalation, dogs that showed a positive result
with the antigen solution at concentrations be-
low $10^{-5}$ g protein/ml in the skin test were
used as naturally sensitized dogs. *Ascaris suum*
antigen inhalation was carried out only once in
each dog.

The results shown in the figures are express-
ed as mean values ± S.E. Statistical analyses
were made by Duncan's test.

**RESULTS**

*Vagal reflex during bronchoconstriction*

Inhalation of saline solution in the bronchial
side had no effect on the bronchial muscu-
lature and the other parameters measured.
Typical responses of ventilation overflow and
intratracheal pressure to inhalation of a
0.00125% solution of histamine for 10 min to
the bronchial side are shown in Fig. 1. Histam-
mine inhalation induced an increase in intra-
tracheal pressure, viz., reflex tracheal constri-
tion following an increase in ventilation over-
flow, viz., bronchoconstriction. The reflex
tracheal constriction occurred after a time lag
following the bronchoconstriction. Both the
reflex tracheal constriction and bronchocon-
striction showed the maximum response near
the end of histamine inhalation, and therefore,
together with the end of inhalation, they
showed a gradual recovery. An infusion of 5
µg/min of atropine to the tracheal site
changed the reflex tracheal constriction by histamine inhalation into a tracheal dilatation (Figs. 1 and 2(A)). The reflex dilatation occurred after a time lag following bronchoconstriction and recovered with the disappearance of bronchoconstriction. The basal tonus of the bronchial musculature and the bronchial constriction induced by histamine inhalation were unaffected by the atropine infusion. The magnitude of the dilatation was smaller than that of the reflex tracheal constriction. The reflex tracheal dilatation in the presence of atropine was abolished by the combination of 100 μg propranolol and transections of both the bilateral superior laryngeal nerves and the spinal cord at the C1 level (Fig. 1).

_Ascaris suum_ antigen inhalation for 10 min (3 mg protein) to naturally sensitized dogs caused a reflex tracheal constriction. The bronchoconstriction and reflex tracheal constriction induced by antigen inhalation were more potent than those by histamine inhalation. The bronchoconstriction showed the maximum response near the end of antigen inhalation, whereas the reflex tracheal constriction tended to recover during the antigen inhalation. With the atropine infusion at a rate of 5 μg/min to the tracheal site, the reflex tracheal dilatation was induced by the antigen inhalation (Fig. 2). The reflex dilatation recovered with the disappearance of bronchoconstriction. This reflex dilatation was abolished by the combination of 100 μg propranolol and transections of both the bilateral superior laryngeal nerves and the spinal cord at the C1 level as in the case of histamine inhalation.

**Intervention of inhibitory nerves in the reflex tracheal constriction**

The reflex tracheal constriction induced by 0.00125% histamine inhalation was significantly increased with an application of 100 μg propranolol to the tracheal site. Furthermore, the reflex tracheal constriction was further enhanced by the combination of 100 μg propranolol and transection of the spinal cord at the C1 level. On the other hand, the bronchoconstriction induced by histamine inhalation was unaffected by 100 μg propranolol and transection of the spinal cord at the C1 level (Fig. 3(A)).

The reflex tracheal constriction induced by antigen inhalation also tended to increase by 100 μg propranolol and transection of the spinal cord at the C1 level, while the bronchoconstriction by the antigen inhalation was unaffected as in the case of histamine inhalation (Fig. 3(B)).
DISCUSSION

We previously devised a preparation for evaluating the vagal reflex-induced tracheal response (10). In the present study, using this preparation, it was observed that the inhalation of histamine aerosol into the bronchial site caused a bronchoconstriction followed by a reflex tracheal constriction. The reflex tracheal constriction was also observed during the inhalation of Ascaris suum antigen. The antigen-induced bronchoconstriction was reduced by vagotomy or vagal blockade with nerve cooling (7, 9). The present observation of the reflex component induced by antigen inhalation may indicate a prominent role of the vagal reflex in asthmatic airway constriction.

The reflex tracheal constriction induced by histamine inhalation was changed into a tracheal dilatation by atropine infusion to the tracheal site, indicating that not only the reflex tracheal constriction but also reflex dilatation, which is usually masked by constriction,
may occur simultaneously. It has been reported that stretch receptors induce a reflex relaxation of airway smooth muscle (14). Bartlett et al. (13) demonstrated that the activities of stretch receptors increased during airway constriction. Thus, it is indicated that airway stretch receptors may play a role in a mechanism limiting bronchoconstriction (14). Therefore, the reflex tracheal dilatation during bronchoconstriction induced by histamine or antigen inhalation may result from activation of stretch receptors in the bronchi.

The reflex tracheal dilatation induced by antigen inhalation was more potent than that by histamine inhalation. This discrepancy seems to come from the difference in the degree of the reflex tracheal constriction following bronchoconstriction, because the antigen inhalation may release various chemical mediators.

In the present study, we observed that the antigen-induced reflex tracheal constriction tended to recover during the antigen inhalation. Thus, there is no clear difference in the recovery of the reflex constriction between the histamine and antigen inhalations. Although the reason for this result is not clear at present, one possible explanation is that the recovery may be related to the strength of the reflex tracheal dilatation. In the case of histamine inhalation, it may be thought that reflex tracheal dilatation was small and was not sufficient to lead to restoration of tracheal constriction during the inhalation.

The reflex dilatation was abolished by the combination of propranolol and transections of both the bilateral superior laryngeal nerves and the spinal cord at the C1 level. It has been demonstrated that the canine tracheal smooth muscle is dilated by sympathetic neuronal stimulation (20, 21) and that the activation of sympathetic nerves reduces histamine-induced tracheal constriction (22). Thus, the sympathetic neuronal pathway is considered as one of the inhibitory nervous systems on the canine trachea. In addition, a previous study has shown the possible involvement of non-adrenergic nerves, as an efferent pathway other than sympathetic nerves, which run in the bilateral superior laryngeal nerves and the spinal cord in reflex tracheal dilatation caused by lung inflation (17). It has been demonstrated that airway stretch receptors respond to both positive and negative transmural pressure (23, 24), and pulmonary stretch receptors are well-known to be stimulated by lung inflation. Therefore, sympathetic and non-adrenergic nerves on the trachea may mediate the reflex tracheal dilatation caused by histamine- or antigen-induced bronchoconstriction as well as that caused by lung inflation. In the present study, the quantitative ratio of the involvements of sympathetic and non-adrenergic nerves in the reflex dilatation could not be estimated because the experiment with a blockade of nonadrenergic nervous system was not done.

The reflex tracheal constriction induced by histamine inhalation was potentiated by propranolol. Diamond (25) showed a potentiation of the bronchomotor response to histamine by β-adrenergic antagonists. McCulloch et al. (16) found evidence for a sympathetic bronchodilator reflex following bronchoconstriction induced by histamine. Therefore, the sympathetic nervous system in the trachea may serve to attenuate the reflex tracheal constriction induced by histamine inhalation. Because the tracheal constriction by Ascaris suum antigen inhalation also tended to be enhanced by an application of propranolol, this kind of sympathetic nerves-mediated inhibitory tracheal reflex response might also occur during asthmatic bronchoconstriction. Furthermore, the reflex tracheal constriction induced by histamine or antigen inhalation under β-blockade was further potentiated by transection of the spinal cord. These results suggest that nonadrenergic nerves contained in preganglionic sympathetic nerves (11) may also limit the reflex tracheal constriction.

On the other hand, the bronchoconstriction induced by histamine or antigen inhalation was not enhanced by a treatment with propranolol or transection of the spinal cord. Because propranolol was applied locally to the
Inhibitory Reflex in Airway

tracheal site in this study, enhancement of the bronchoconstriction by \( \beta \)-blockade was not observed. Since McCulloch et al. (16) demonstrated a potentiation of histamine-induced bronchoconstriction by propranolol in dogs, it is presumed that sympathetic nerves reflexly counteract not only tracheal constriction but also bronchoconstriction through the activation of \( \beta \)-adrenoceptors. Furthermore, the bronchoconstriction by histamine or antigen inhalation was also not affected by transection of the spinal cord. It is indicated that nonadrenergic nerves may have much less involvement in the bronchoconstriction than in the tracheal constriction. Probably, the inhibitory reflex mediated by nonadrenergic nerves may be masked by the bronchoconstriction so that histamine and antigen caused a very potent bronchoconstrictions.

In both experiments of histamine and antigen inhalations, potentiations of reflex tracheal constriction induced by \( \beta \)-blockade and transection of spinal cord together with \( \beta \)-blockade were larger than the reflex dilatation under atropine infusion. Therefore, it may be speculated that first, because prejunctional \( \beta_2 \)-receptors inhibit acetylcholine release from cholinergic nerve endings (26), propranolol enhances the release in the trachea; and second, \( \sigma \)-mediated tracheal constrictions appeared by \( \beta \)-blockade (27).

In conclusion, during histamine- or antigen-induced bronchoconstriction, the reflex tracheal dilatation which is thought to be mediated by the sympathetic nervous system and partly by the nonadrenergic nervous system may occur simultaneously with the reflex tracheal constriction. The inhibitory reflex response may thus play a role in a mechanism limiting the airway constriction.
