Nitrogen doped graphene with diamond-like bonds achieves unprecedented energy density at high power in a symmetric sustainable supercapacitor†

Veronika Šedajová, Aristides Bakandritsos, Piotr Błoński, Miroslav Medved, Rostislav Langer, Dagmar Zaoralová, Yuri Ugolotti, Jana Dzibelová, Petr Jakubec, Vojtěch Kupka and Michal Otyepka

Supercapacitors have attracted great interest because of their fast, reversible operation and sustainability. However, their energy densities remain lower than those of batteries. In the last decade, supercapacitors with an energy content of ~110 Wh L⁻¹ at a power of ~1 kW L⁻¹ were developed by leveraging the open framework structure of graphene-related architectures. Here, we report that the reaction of fluorographene with azide anions enables the preparation of a material combining graphene-type sp² layers with tetrahedral carbon–carbon bonds and nitrogen (pyridinic and pyrrolic) superdoping (16%). Theoretical investigations showed that the C–C bonds develop between carbon-centered radicals, which emerge in the vicinity of the nitrogen dopants. This material, with diamond-like bonds and an ultra-high mass density of 2.8 g cm⁻³, is an excellent host for the ions, delivering unprecedented energy densities of 200 Wh L⁻¹ at a power of 2.6 kW L⁻¹ and 143 Wh L⁻¹ at 52 kW L⁻¹. These findings open a route to materials whose properties may enable a transformative improvement in the performance of supercapacitor components.

Broader context
Modern society relies on electricity. The demand is bound to grow due to the increasing electromobility, the number of mobile devices, and extending the networks for the internet of things. The depleting reserves of fossil-based energy resulted in efforts to support renewable resources, which are, however, intermittent in their production. These facts call for the development of electrochemical energy storage devices with improved performance, safety, eco-friendliness, and lower cost in order to contribute to the goal of the United Nations for affordable, reliable, and sustainable energy. Lithium-ion batteries have matured and currently dominate the field. Nevertheless, carbon-based supercapacitors offer independence of critical elements, alongside safety, long life-cycle, and ultrafast charging–discharging. Here, we present a nitrogen superdoped graphene material with diamond-like interlayer bonds that dramatically increases the energy content, which can be stored per volumetric unit of the electrode—the Achilles heel of contemporary supercapacitors. The electrode displays an ultrahigh mass density compared to porous carbons, keeping intact its ability to host the electrolyte ions—the energy carriers. Consequently, a supercapacitor device made from this electrode delivers energy density twice as high as that of top-rated materials and several-fold higher than commercial supercapacitor carbons, thus enhancing the performance of supercapacitor components.

1. Introduction

Supercapacitors are energy storage devices with remarkable qualities including fast charging/discharging (i.e. high power) and extralong cycle-life. Unfortunately, the energy density of the best existing supercapacitors (i.e. their ability to store charge/energy) is low. Commercial supercapacitors have cell-specific energies (and energy densities) of 10 Wh kg⁻¹ (5–8 Wh L⁻¹), while lead–acid batteries offer 20–35 Wh kg⁻¹ (40–80 Wh L⁻¹) and state-of-the-art Li-ion batteries achieve ~150 Wh kg⁻¹ (~250 Wh L⁻¹). However, Li-ion batteries
2. Results and discussion

Motivated by the importance of fluorine and radical chemistry in the synthesis of sp$^3$-rich carbon materials and by the high density of such materials, we hypothesized that fluorographene chemistry could produce carbon derivatives with high mass densities. This hypothesis was strengthened by the fact that in (C$_2$F)$_m$ whereby fluorine atoms occupy one side of every other carbon sheet in an FCCF manner, the carbon atoms in between adopt a diamond-like structure, ascribing high mass density. The formation of similar sp$^3$-rich structures was also verified theoretically and experimentally for bilayer graphene. Despite their high mass density, fluorocarbons are large band-gap insulators and lack sites capable of interacting strongly with ionic species and facilitating their transport. However, because the defluorination and functionalization of fluorographene is known to occur via radical reactions propagated by fluorine elimination, these processes could potentially be exploited to drive sp$^3$-C-C bond formation and create graphene-based materials with high mass density.

To investigate this hypothesis, we experimentally and theoretically probed the reaction of few-layered fluorographene with sodium azide as a defluorinating agent that could at the same time introduce nitrogen atoms into the formed structure. This would increase the polarity of the carbon surface and create vacancies, as previously observed following reactions of fluorographene with various nitrogen-containing nucleophiles. Sonicated bulk graphite fluoride reacted very efficiently with NaN$_3$ in dimethylformamide at 130 °C, resulting in nitrogen superdoping. X-ray photoelectron spectroscopy (XPS) revealed a decrease in the material's content of F atoms after a reaction time of 4 h and almost complete elimination of F after 72 h, at which point the material's N content reached 16.1 at% (Fig. 1b and c). This change was reflected in the C 1s regions of the materials' XPS spectra (Fig. 1c): the initially
F-bonded carbon atoms of fluorographene, with binding energies above 289.5 eV, were transformed into (i) aromatic sp² carbons (284.7 eV, 45%), (ii) non-functionalized sp³ carbons (285.5 eV, 25%), and (iii) nitrogen bonded carbons (286.6 eV, 19%). The other components in this spectral region were attributed to small amounts of residual fluorine and oxygen from the environment. The HR-XPS spectra of the N 1s envelope (Fig. S1, ESI†) revealed the presence of nitrogen atoms in pyridinic and pyrrolic configurations (or protonated and non-protonated N centres), as well as a very small number of graphitic nitrogens (44, 49, and 7 at%, respectively). The dominance of pyridinic and pyrrolic nitrogens is consistent with the vacancies present in the parent material and with the extensive development of such vacancies during defluorination.

The ¹H → ¹³C CP MAS solid-state NMR spectra of the GN3-4 h intermediate and GN3 show peaks at 34 ppm (Fig. 1e). Chemical shifts in this range are typical for non-functionalized and non-nitrogen bonded sp³ carbons in diamond and diamond-like carbon materials. This peak was stronger in the spectrum of GN3 than the GN3-4 h intermediate, indicating that these sp³ carbons formed gradually as the reaction progressed. Furthermore, the peaks centred at 124 and 154 ppm indicate the presence of a π-conjugated aromatic network and aromatic >C=N moieties (pyridinic and pyrrolic), respectively. The CP MAS of the starting GF revealed peaks corresponding to CF₂ (117 ppm) and CF (94 ppm) groups, typical for FG. Such non-functionalized tetrahedral carbons at 34 ppm are not detected in graphene oxide, reduced graphene oxide, or graphene. The reaction’s progress was also verified by infra-red spectroscopy (Fig. 1f). Specifically, the bands of the CF and CF₂ groups of GF (1200 and 1305 cm⁻¹, respectively) were progressively replaced with...
bands at 1580 and 1210 cm$^{-1}$ (characteristic of aromatic carbon rings$^{44}$), indicating the formation of an sp$^2$ network. Additional aromatic-ring vibrations, appearing at 1400 cm$^{-1}$, could be ascribed to heteroatom substitution (e.g. with pyridinic nitrogens$^{44,45}$), as suggested by theoretical calculations.$^{46,47}$ The Raman spectrum of GN3 featured broad D and G bands at 1300 and 1590 cm$^{-1}$, respectively, and an $I_D/I_G$ ratio of 1.3, which remained unchanged even after heating at 1000 °C in an argon atmosphere (Fig. S2, ESI†), indicating the presence of a large number of non heat-susceptible sp$^3$ carbons and non-healable defects (i.e. vacancies). Raman bands and X-ray diffraction peaks (XRD) deconvolution performed on GN3, and on the commercial porous carbon for comparison (Fig. S3 and S4, ESI†), showed that the GN3 displays a disordered structure with randomly developed tetrahedral C–C bonds. Results also highlighted the very small planarity of the aromatic areas, with a lateral size ($L_a$) of ca. 4 nm (Fig. S3 and S4, ESI†), and comments in the caption). Further insights into the N-doping of fluorographene with NaN$_3$ were obtained through density functional theory (DFT) calculations. The N$_3^-$ anion initiated the reaction by nucleophilic attack on carbon radical defects, leading to N$_2$ release and fluorine elimination (Fig. S5, ESI†). The attachment of azide groups in the initial stages of the reaction was confirmed by the infra-red spectrum of the 2 h intermediate (Fig. 1f). High-resolution transmission electron microscopy (HR-TEM, Fig. 2a and b) revealed that GN3 indeed exists as sheets with patches and holes.

Energy dispersive X-ray spectroscopy (EDXS) elemental mapping with high-angle annular dark-field scanning transmission electron microscopy (HAADF-STEM, Fig. 2c) showed that the GN3 sheets (Fig. 2d) are densely and homogeneously covered with nitrogen (Fig. 2e). Thermogravimetric and evolved gas analyses in air (Fig. S6, ESI†) indicated that these nitrogen atoms were embedded in the lattice rather than being out-of-plane functionalities, because emission of NO gas (m/z = 30) peaked at very high temperature (675 °C), at which CO$_2$ emission also took place due to carbon lattice decomposition.

To better understand the formation of the tetrahedral C–C bonds, theoretical models of GN3 sheet fragments were studied using spin-polarized DFT (Fig. 3), consistent with the experimental findings (i.e. containing vacancies and nitrogen dopants mainly in pyridinic and pyrrolic configurations, Fig. 3). Remarkably, the system relaxed into a thermodynamically stable structure with spontaneously formed tetrahedral sp$^3$ C–C bonds, verifying the experimental NMR findings. The bonds were formed between the carbons in the pyridinic vacancies, where radicals were centred (highlighted by spheres in Fig. 3). Similar sp$^3$ bonding was suggested to form after the introduction of atomic vacancies and pyrrolic N atoms by N-ion beam irradiation of graphene sheets, which creates carbon atoms with dangling bonds (radicals) around the vacancies.$^{48}$ Films of GN3 or GN3 with additives (polymer binder 10%; conductive additive 5%) were formed by pasting slurries onto 15 μm-thick Al foils for density measurements and preparation.
of supercapacitor electrodes (ESI,† Methods). Scanning electron microscopy (SEM, Fig. 4a–c) showed that compression at 80 kN for 1 minute (∼65 MPa) reduced a ca. 10 μm thick film of GN3 to a thickness of 2 μm (Fig. 4d–f). From thickness measurements performed using SEM and a digital micrometer (Fig. S7c and d, ESI†), the density of these films consistently reached values of 2.7–2.8 g cm⁻³, compared to ∼0.5 g cm⁻³ before pressing. The same mass density was also attained for a high-mass loading electrode (8.3 mg cm⁻², Fig. S7i and j, ESI†). The NMR spectrum of the pressed material was identical to that before pressing, indicating that pressing caused only bed consolidation, and not formation of bonds. Five GN3 batches from different reactions were measured to determine the mass density; it should be noted that densities were only measured after dialysis of GN3. Control tests were performed using the same procedure with Al foil alone (Fig. S7a and b, ESI†) and with commercial carbons of high surface area (Fig. S7e–h, ESI†), namely porous carbon (PC) from ACS Material (0.3 g cm⁻³, 2000 m² g⁻¹ according to N₂ BET) and YP-80F Kuraray carbon (KC) (0.6 g cm⁻³, 2363 m² g⁻¹ according to N₂ BET; also measured in-house, Fig. S8b and d, ESI†). The thickness measurements for the PC carbon were cross-checked by SEM (Fig. S9, ESI†). Results verified that no compression took place for Al foil, and that all mass density calculations for the commercial carbons after their pressing matched those given by the provider. Moreover, we performed elemental analysis for Na showing that 0.02 mass% of sodium remained in GN3, and therefore, the respective contribution in mass density of the material is negligible. The surface area of GN3 determined from the N₂ sorption isotherm using BET equation was only 128 m² g⁻¹, (Fig. S8a and c, ESI†). The surface area determined by methylene blue sorption was 300 m² g⁻¹ (Fig. S10, ESI†), suggesting that under solvated conditions (as in an electrolytic supercapacitor cell), charged species/molecules, like methylene blue in this case, may penetrate into the structure of GN3. Interestingly, preliminary electrochemical testing of GN3 showed that pressing did not affect its charge storage properties; in fact, pressing increased the capacitance relative to the non-pressed electrode (Fig. S11, ESI†).

The electrochemical properties of GN3 were studied in a symmetric full cell using as the electrolyte the IL 1-ethyl-3-methylimidazolium tetrafluoroborate (EMIM-BF₄) with 1,1,2,2-tetrafluoroethyl-2,2,3,3-tetrafluoropropyl ether (TTE) in a 9:1
ratio. The cyclic voltammograms (CVs, Fig. 5a) were quasi-rectangular in shape with minor redox peaks, probably due to the nitrogen lattice atoms of the GN3 material. This shape was preserved even at very high scan rates (Fig. S12, ESI†), indicating that the system exhibits predominantly capacitive behaviour with fast charge transport in the material and at the interfaces. These features were verified by galvanostatic charge/discharge measurements (GCD, Fig. 5b), which yielded linear and symmetric profiles (124 s charging, 118 s discharging at 2 A g⁻¹, 95% energy efficiency). The efficiency improved to 100% at 20 A g⁻¹ (22 s charging, 22 s discharging). At 1 A g⁻¹, the GN3 cell achieved an ultrahigh energy density of 197.6 W h L⁻¹ at a power of 2.6 kW L⁻¹. At 20 A g⁻¹, the energy density remained high at 143.5 W h L⁻¹, while the power density jumped to 51.8 kW L⁻¹ (Fig. 5c).

For benchmarking, the carbons PC and KC (the latter widely used in commercial supercapacitors) were evaluated under identical conditions. GN3 had a significantly better discharging time (Fig. 5d) than PC and KC, and its performance was superior in both volumetric and gravimetric terms (Fig. 5e), which is impressive given the dramatic differences in the materials’ BET surface areas. The cycling stability test of the GN3 material showed capacitance retention of 100% after 10 000 cycles at 20 A g⁻¹ (Fig. 5f) and 98% after 14 000 cycles at 5 A g⁻¹ (Fig. S15, ESI†). Rate testing of the GN3 cell showed that 76% retention of its capacitance at 40 A g⁻¹ (Fig. 6a). A similar (70%) capacitance retention was achieved at 40 A g⁻¹ for a cell made with exfoliated graphene-mediated HI-reduced graphene oxide (EGM-GO), which contained 50% exfoliated graphene.

For comparative purposes, reported capacitance retention values for other high-performance graphene-based electrodes are ca. 65% at 40 A g⁻¹ for liquid-mediated densified graphene, 18 70% at 40 A g⁻¹ for holey graphene, 19 57% at 10 A g⁻¹ for capillary-densified graphene, 21 and 77% at 20 A g⁻¹ for vertically aligned graphene electrodes (a much more conductive aqueous electrolyte was used in the latter case, which unfortunately keeps energy content low). These
Comparisons highlight the excellent charge transport properties of GN3, which are also reflected in its electrochemical impedance spectroscopic features before and after cycling (Fig. 6b). Based on the modified Frumkin–Melik–Gaykazyan circuit (Fig. S17, ESI†), the intersection of the Nyquist plot with the real axis at the start of the high frequency region corresponded to an equivalent series resistance ($R_s$) of 3.9 $\Omega$ before cycling, which was only marginally increased to 4.4 $\Omega$ after 10 000 cycles.

Furthermore, the total absence of semicircles in the high frequency region indicated a very low charge transfer resistivity ($R_{ct}$) in the bulk material and at the interfaces.\(^{19,52}\) The almost vertical slope of the spectrum in the low frequency region (on the right of the x-axis) suggested a highly capacitive behaviour and effective ionic charge transport in the bulk of the electrode material.

Volumetric performance is particularly important for devices in the modern portable energy storage landscape;\(^2,4,13,14,20,23\) both energy and power density are desired. The former directly affects the amount of energy that can be stored, while high power density enables fast charging and discharging. Energy density is the Achilles heel of supercapacitors, whereas high power densities are one of their greatest strengths, which must be preserved. The GN3 cell (Fig. 5c and Fig. S18, ESI†) demonstrated ground-breaking performance by delivering both ultrahigh energy density and power density. Specifically, its energy density was ca. 200 W h L\(^{-1}\) at a...
power of 2.6 kW L\(^{-1}\), 170 W h L\(^{-1}\) at 5.2 kW L\(^{-1}\), and 143 W h L\(^{-1}\) at 52 kW L\(^{-1}\). To set these results into the context of the current state of the art, they are presented alongside literature data on top-performing materials in Fig. 7a. When making these comparisons, care was taken to ensure that the same set of equations and metrics were used in all cases.\(^{53-55}\) The equations from ref. 23 were used, as described in the experimental section. The comparisons highlight the transformative performance of GN3: not only does it have a higher energy density than the previously best-in-class EGM-GO electrode (170 W h L\(^{-1}\) for GN3 vs. 113 W h L\(^{-1}\) for EGM-GO\(^{23}\)), but this energy could be delivered at a power of 5.2 kW L\(^{-1}\) compared to 0.9 kW L\(^{-1}\). Importantly, the GN3 cell could also be operated at mass loadings of up to 10 mg cm\(^{-2}\), demonstrating almost identical capacitance (Fig. 7b) at a temperature of 38 °C, which is in the range typically used to evaluate energy storage devices,\(^{56-59}\) and 81% retention at the same testing conditions as the low mass-loading supercapacitor cell (see experimental part, ESI\(^{1}\)). The coin cell shown in Fig. 7c and d, was constructed with a commercial ultrathin membrane operating a 4 V LED lamp. Successful operation of carbon materials with such highly attractive features lays the ground for the fabrication of competitive, commercially relevant cells.

3. Conclusions

We have discovered a new class of carbon-based materials comprising nitrogen doped graphene with diamond-like tetrahedral bonds for high energy density supercapacitor electrodes that are significantly more dense than comparable materials prepared by mechanical compression,\(^{17}\) capillary densification,\(^{18}\) and other methods.\(^{19,23}\) The new materials are prepared by leveraging the radical-based chemistry of fluorographene, which enables the fruitful combination of sp\(^2\) and sp\(^3\) carbon bonds in the same network, along with very high nitrogen doping and vacancies. This hybrid carbon achieves mass densities of 2.8 g cm\(^{-3}\), while retaining efficient charge transport, ion penetration, diffusion, and storage. Therefore, cells with electrodes made from these materials offer ground-breaking energy storage capability at very high charging/discharging rates. The discovery of this class of materials will spur intense research on other high-density conductive carbon materials with different functionalities, with the aim of further increasing the competitiveness of supercapacitors in the portable energy storage landscape.
