Rethinking Evaluation in ASR: Are Our Models Robust Enough?

Abstract

Is pushing numbers on a single benchmark valuable in automatic speech recognition? Research results in acoustic modeling are typically evaluated based on performance on a single dataset. While the research community has coalesced around various benchmarks, we set out to understand generalization performance in acoustic modeling across datasets – in particular, if models trained on a single dataset transfer to other (possibly out-of-domain) datasets. Further, we demonstrate that when a large enough set of benchmarks is used, average word error rate (WER) performance over them provides a good proxy for performance on real-world data. Finally, we show that training a single acoustic model on the most widely-used datasets – combined – reaches competitive performance on both research and real-world benchmarks.

1 Introduction

Progress in automatic speech recognition (ASR) is measured on the validation and test sets of standard datasets. However, most acoustic models (AMs) are often developed and tuned on a single dataset and transfer poorly to other datasets. Moreover, most large standard benchmarks have similar domains and recording conditions. These factors lead to siloed ASR research. A unified benchmark comprised of conversational, oratory, and read speech with varied recording conditions and noise would certainly serve the research community well; here, however, we study how the currently-popular public benchmarks can be used to gauge model generalization performance.

Our approach constructs a validation procedure – using only public datasets – that is a better predictor of overall and domain transfer performance than datasets taken in isolation. We train the same state-of-the-art model architecture on different benchmarks pushing for best performance on each benchmark separately. We also jointly train a model on all datasets. Given the transfer performance on test sets, we can ascertain which test sets are good proxies for transfer performance as well as which training sets can produce the best-performing models. This informs us on the robustness of various datasets in transfer and which test sets are the best predictors of ASR performance in others. Finally, we look at the performance, in transfer only, on our in-house ASR datasets. This informs us about which sets of test sets should be used if one wants to transfer to a wide range of conditions of speech.

2 Related Work

Previous works that study transfer in ASR include [Ghahremani et al., 2017] that studied transferring varying number of layers trained out-of-domain, from SwitchBoard to AMI-IHM or from LibriSpeech to AMI-IHM. In this paper...
as in ours, a joint model trained on multiple out-of-domain datasets exhibits better transfer. In the context of the Arabic MGB-3 challenge, [Manohar et al., 2017] transferred AMs trained on broadcast TV to Youtube videos, with a different setting than here as the training transcriptions were noisily labeled. Distillation was used to improved transfer in [Asami et al., 2017], where the soft-target part of the distillation loss may help with regularization. For another kind of transfer in [Kunze et al., 2017], the authors transferred LibriSpeech trained wav2letter [Collobert et al., 2016] models to German by fine-tuning them on German, with better performance than training from scratch. Very recently, [Szymański et al., 2020] point out some limitations of current ASR benchmarks, and propose guidelines to create multi-domain datasets. Finally, while DeepSpeech 2 [Amodei et al., 2016] did not focus their study on transfer, we train a single AM on multiple datasets at once, as they did.

3 Domain Transfer

In order to study transfer across datasets and conditions, we do a systematic analysis. In all our experiments, we use a single Transformer-based AM architecture with 270M parameters, to make our results comparable across the board. We train multiple single-dataset baselines as well as one joint model trained on all datasets at once. We then evaluate this set of models on all the validation and test sets, to measure how each "in-domain" model transfers to "out-of-domain" datasets. From this, we analyze which datasets suffer more acutely from "domain overfitting." Evidently, it is difficult to separate the "in-domainness" and size of a dataset; e.g., we cannot directly compare results on WSJ (80h) to ones on LibriSpeech (960h). We also fine-tune our joint model on the transfer dataset with 1h, 10h, and 100h of in-domain data. Finally, we examine how our models transfer to real data and in the process observe that public validation and test sets performance is predictive of the transfer performance of a model to real data.

4 Experiments

4.1 Datasets

To measure domain transfer, we restrict experiments to use only datasets in English, for which there exist several commonly-used and publicly available datasets with hundreds hours of transcribed audio. Validation sets from each dataset are used to optimize model configurations and to perform all hyper-parameter tuning, while test sets are used for final evaluation only.

**LibriSpeech (LS)** [Panayotov et al., 2015] consists of read speech from audiobook recordings. We use standard split of train, validation (dev-clean, dev-other) and test sets (test-clean, test-other).

**SwitchBoard & Fisher (SB+FSH)** consists of conversational telephone speech. To create a training set, we combine Switchboard [Godfrey and Holliman, 1993] and Fisher [Cieri et al., 2004, 2005b]. We use RT-03S [Fiscus et al., 2007] as the validation set; test sets are the Hub5 Eval2000 [LDC et al., 2002] data with two subsets, SwitchBoard (SB) and CallHome (CH). For the data processing and evaluation, we follow the recipe provided by Kaldi [Povey and other, 2011].

**Wall Street Journal (WSJ)** [Garofolo et al., 1993, LDC and Group, 1994, Woodland et al., 1994]. We consider the standard subsets si284, nov93dev and nov92 for training, validation and test, respectively. We remove any punctuation tokens from si284 transcriptions when used for training.

**Mozilla Common Voice (CV)** project [Ardila et al., 2020]. The CV dataset consists of transcribed audio in various languages where speakers record text from Wikipedia. Anyone can submit recorded contributions; as a result, the dataset has a large variation in quality and speakers. We use the English dataset[2], where data splits are provided therein.

**TED-LIUM v3 (TL)** [Hernandez et al., 2018] is based on TED conference videos. We use the last edition of the training set from this dataset (v3), for which the validation and test sets are kept consistent (and thus numbers are comparable) with the earlier releases. We follow the Kaldi recipe [Povey and other, 2011] for data preparation.

**Robust Video (RV)** is our in-house English video dataset, which are sampled from public social media videos and aggregated and deidentified before transcription. These videos contain a diverse range of speakers, accents, topics, and acoustic conditions making ASR difficult. The test sets are composed of clean, noisy and extreme with extreme being the most acoustically challenging subset among them. The validation set comprises of data from clean and noisy subsets.

---

2 June 22nd 2020's snapshot: [https://tinyurl.com/cvjune2020](https://tinyurl.com/cvjune2020). Transcriptions contain upper-case and non-English characters and punctuation. To have similar transcription normalization as in other datasets, we normalize the text for all splits: lower-casing, Unicode normalization, removing punctuation and non-English tokens, and mapping common abbreviations (e.g. “mr.” to “mister”).
Rethinking Evaluation in ASR: Are Our Models Robust Enough?

Table 1: Statistics on datasets.

| Data    | kHz | Train (h) | Valid (h) | Test (h) | Speech |
|---------|-----|-----------|-----------|----------|--------|
| WSJ     | 16  | 81.5      | 1.1       | 0.7      | read   |
| TL      | 16  | 452       | 1.6       | 2.6      | oratory|
| CV      | 48  | 693       | 27.1      | 25.8     | read   |
| LS      | 16  | 960       | 5.1+5.4   | 5.4+5.4  | read   |
| SB+FSH  | 8   | 300+2k    | 6.3       | 1.7+2.1  | convers.|
| RV      | 16  | 5k        | 14.4      | 18.8+19.5+37.2 | diverse |

Figure 1: Distribution of the mean normalized energy of 80 filterbanks on all the public validation sets we used, for 16kHz audio (dashed) and 8kHz audio (solid).

Table 2: Perplexity (including out-of-vocabulary words) of word-level LMs. We use 4-gram LM for WSJ, LS, SB+FSH, and 5-gram for TL, CV.

| Data/Vocab | in-dom. n-gram Valid | Test | in-dom. Transf. Valid | Test | CC 4-gram Valid | Test |
|------------|-----------------------|------|-----------------------|------|------------------|------|
| WSJ/162K   | 159                   | 134  | 83                    | 65   | 297              | 285  |
| TL/200k    | 119                   | 149  | 79                    | 81   | 142              | 136  |
| CV/168K    | 359                   | 329  | 256                   | 240  | 213              | 157  |

4.2 Unifying Audio

Datasets have different sample rate as shown in Figure 1 and vary significantly in the validation/test set size as shown in Table 1. One challenge when training joint models on combined audio data is determining the frequency range that the filterbanks should span to compute log-mel spectrogram features. For example, as SwitchBoard and Fisher have the lowest sample rate of 8kHz, filterbanks can span up to 4kHz and any spectrogram features beyond 4kHz cannot be determined accurately [Shannon, 1949], as shown in Figure 1. Since we require the same set of filterbanks for joint training across all datasets, we use the minimum sample rate over all datasets (8kHz) and use this setup for training both baseline models on individual datasets as well as joint models. In this case the distribution of mean normalized energy of filterbanks for all the samples in each dataset is similar.

For datasets with higher original sample rates, downsampling negatively affects performance; for LS, for example, the WER is absolute 0.3% and 0.2% worse on dev-other, without and with beam-search decoding, respectively. For all experiments we compute 80 log-mel spectrogram features for a 25ms sliding window, strided by 10ms. All features are normalized to have zero mean and unit variance per input sequence before feeding into the neural network.

4.3 Baselines and Joint Model

Acoustic Model (AM) All models are trained with Connectionist Temporal Classification [Graves et al., 2006] and the network architecture follows [Synnaeve et al., 2019]: the encoder of our AMs is composed of a convolutional frontend (1-D convolution with kernel-width 7 and stride 3 followed by GLU activation) followed by 36 4-heads Transformer blocks [Vaswani et al., 2017]. The self-attention dimension is 768 and the feed-forward network (FFN) dimension is 3072 in each Transformer block. The output of the encoder is followed by a linear layer to the output.
classes. We use dropout after the convolution layer. For all Transformer layers, we use dropout on the self-attention and on the FFN, and layer drop [Fan et al., 2020], dropping entire layers at the FFN level. Dropout and layer dropout values are tuned for each model separately. Token set for all AMs consists of 26 English alphabet letters, augmented with the apostrophe and a word boundary token. The popular approach with word-pieces as tokens set we found to be not suited as intersection between word-pieces constructed on every training set less than 50%. Thus the question and pruning of all 3,4-grams appearing once. Perplexity of all LMs is shown in Table 2.

Language Model (LM) and Beam-search Decoding For each dataset we train in-domain word-level n-gram LM using KenLM toolkit [Heafield, 2011] and Transformer LM as in [Synnaeve et al., 2019]. In-domain LM training uses: for WSJ and LS – their provided LM data; for CV, SB+FSH, and RV – train transcriptions only; for TL – both train transcriptions and provided LM data. We also train a 4-gram LM on Common Crawl (CC) data with 200k top words and pruning of all 3,4-grams appearing once. Perplexity of all LMs is shown in Table 2. We rely on the one-pass beam-search decoder from the wav2letter++ [Collobert et al., 2016] (lexicon-based with a n-gram LM) and second-pass rescoring with a Transformer LM following [Synnaeve et al., 2019].

Joint Model We adopt the same AM architecture described above but with less regularization when training on the combination of all the datasets. We weight each sample equally, i.e. each sample from each dataset is fed into the model once in each epoch.

State-of-the-Art Models In Table 3 for each dataset, we report known state-of-the-art models with in-domain LMs.

Table 3: WER of models evaluated on all datasets (downsampled to 8kHz) with a greedy decoding and no LM (top), with in-domain n-gram LM beam-search decoding (middle) and with additional second-pass rescoring by in-domain Transformer LM (below), with beam-search decoding and 4-gram LM for joint model (joint CC). SOTA models are given from WSJ [Hadian et al., 2018], TED-LIUM [Zhou and other, 2020], LibriSpeech [Gulati et al., 2020], SwitchBoard & Fisher [Han et al., 2017]. The average is computed as average of averages for LibriSpeech’s validations/tests, and SwitchBoard’s tests (SB, CH) sets, so as not to weight them more heavily.

|               | WSJ | TL   | CV   | LS   | SB+FSH | average |
|---------------|-----|------|------|------|--------|---------|
|               | dev  | test | dev  | test | dev  | test |
| SOTA          | 2.8  | 5.1  | 5.6  | 1.9  | 3.9   | 8.0    | 5.0    | 9.1    |

4.4 AM Transfer

In general, an AM trained in isolation on a single dataset performs poorly on other datasets, as shown in Table 3. The model trained on WSJ performs the worst (part of the reason could be the smaller amount of training data) for transfer, while other models transfer very well to WSJ. All models transfer poorly to CV and the CV model transfers poorly to other datasets, which may indicate that CV is very different from other benchmarks. From the results on LS, TL and SB+FSH there is a similarity between LS and TL (they transfer the best to each other). There is also a similarity in transfer between SB+FSH and TL benchmarks, however, LS and SB+FSH do not transfer well to each other. When training on all datasets at once, the joint model in Table 3 performs better or close to a single dataset training. This behaviour compared to results on a single dataset training indicates that i) datasets differ from each other and ii) a robust model scoring well on all these benchmarks exists.

In Table 4 we report results of transfer, of those same models trained on public datasets, to our in-house RV dataset. We also report numbers from a baseline system that is trained in-domain on a corresponding training set of 5000h. As for other benchmarks, single dataset training transfers poorly to in-house data, however, the transfer quality varies a lot, having the best results from the TL model. At the same time our joint model, which performs well on each benchmark, transfers really well, stating that i) public datasets could be the good proxy of training data for real-world ASR, ii) improving average performance on public benchmarks leads to improving performance on real-world noisy data. Moreover, fine-tuning of this joint model on 1h closes the gap with the RV baseline model and fine-tuning with 10h or 100h of data and decoding with CC LM surpasses WER compared to the RV baseline model decoded with in-domain LM.

4.5 Transfer with LM

Single-dataset AMs get a boost in WER performance when decoding/rescoring with an in-domain LM, as shown in Table 5. These AMs perform however poorly in transfer domain conditions (see Tables 3 and 4). In contrast, the joint model transfers well to in-house RV data, when decoded with an in-domain LM (see Table 4). Decoding the
joint model with the large generic CC LM leads to WER performance which is overall improved, on both public and in-house RV datasets.

4.6 Predictors of transfer

We performed single variable linear regressions using data from Table 3 lines as datapoints, test set score columns as features, and labels being the same models’ performance in transfer on the average of test clean, noisy, and extreme, from Table 4. Across all datasets, and taken over all trained models, the best “single test set” predictor for out-of-domain performance on RV data is SB with an $r^2 = 0.8$ (rejecting the null hypothesis with $p < 0.001$), the worst single predictor being WSJ’s nov92 with $r^2 = 0.5$ ($p < 0.001$). We also performed multivariate regressions using all the test results from Table 3 and only the results for the models decoded with n-gram LMs. This gives an overspecified problem (more variables: 7, than models: 6), so OLS gives a “perfect” (overfitted, $r^2 = 1$) solution which weights nov92, test-clean, test-other negatively. We repeat this regression with heavy L1 regularization (Lasso, as proxy for L0 norm regularization) and it yields a regression with $r^2 = 0.98$ (although only 6 datapoints) with only 3 test sets weighted non-zero, and positively: TL, CV, and SB. We can conclude that those test sets are the most predictive of the performance in transfer on RV of our Transformer-based AMs decoded with n-grams. A larger study across AMs and LMs variants should provide a more robust conclusion.

5 Conclusion

We studied transfer across five public datasets, as well as transfer to out-of-domain, real-world audio data, for a single AM architecture based on Transformers and with n-gram and Transformer-based LMs for decoding. We showed that no single validation or test set from public datasets is sufficient to measure transfer to other public datasets or to real-world audio data. Our results suggests that ASR researchers interested in producing transferable AMs should, at the very least, report results on SwitchBoard, CommonVoice, and TED-LIUM (v3). Finally, we provided a recipe for a community-reproducible robust ASR model, which can be trained with a couple of public audio datasets, and an LM built on Common Crawl.
