ABSTRACT: Conversion reaction materials (transition metal oxides, sulfides, phosphides, etc.) are attractive in the field of lithium-ion batteries because of their high theoretical capacity and low cost. However, the realization of these materials in lithium-ion batteries is impeded by large voltage hysteresis, high polarization, inferior cycle stability, rate capability, irreversible capacity loss in first cycling, and dramatic volume change during redox reactions. One method to overcome these problems is the introduction of amorphous materials. This work introduces a facile method to synthesize amorphous and crystalline dinickel phosphide (Ni$_2$P) nanoparticle clusters with identical morphology and presents a direct comparison of the two materials as anode materials for rechargeable lithium-ion batteries. To assess the effect of crystallinity and hierarchical structure of nanomaterials, it is crucial to conserve other factors including size, morphology, and ligand of nanoparticles. Although it is rarely studied about synthetic methods of well-controlled Ni$_2$P nanomaterials to meet the above criteria, we synthesized amorphous, crystalline Ni$_2$P, and self-assembled Ni$_2$P nanoparticle clusters via thermal decomposition of nickel−surfactant complex. Interestingly, simple modulation of the quantity of nickel acetylacetonate produced amorphous, crystalline, and self-assembled Ni$_2$P nanoparticles. A 0.357 M nickel−trietylphosphine (TOP) solution leads to a reaction temperature limitation (∼315 °C) by the nickel precursor, and crystalline Ni$_2$P (c-Ni$_2$P) nanoparticle clusters are generated. On the contrary, a lower concentration (0.1 M) does not accompany a temperature limitation and hence high reaction temperature (330 °C) can be exploited for the self-assembly of Ni$_2$P (s-Ni$_2$P) nanoparticle clusters. Amorphous Ni$_2$P (a-Ni$_2$P) nanoparticle clusters are generated with a high concentration (0.714 M) of nickel−TOP solution and a temperature limitation (∼290 °C). The a-Ni$_2$P nanoparticle cluster electrode exhibits higher capacities and Coulombic efficiency than the electrode based on c-Ni$_2$P nanoparticle clusters. In addition, the amorphous structure of Ni$_2$P can reduce irreversible capacity and voltage hysteresis upon cycling. The amorphous morphology of Ni$_2$P also improves the rate capability, resulting in superior performance to those of c-Ni$_2$P nanoparticle clusters in terms of electrode performance.

1. INTRODUCTION

With global warming and fluctuating oil prices, research on new energy sources that are based on eco-friendly and abundant resources such as solar radiation, wind, and waves has become an important topic worldwide. With these new energy sources, the importance of energy-storage devices is also gradually being recognized. In particular, lithium-ion batteries (LIBs) are promising power sources for not only cell phones and laptops but also electric vehicles and energy storage systems. Many commercial LIBs consist of a LiCoO$_2$ cathode, a carbon anode, and a separator with an electrolyte. To improve the current LIB performance, it is necessary to use new negative electrode materials which have high capacity, low cost, and environmental benignity. Recently, a new reactivity concept based on the reversible electrochemical reaction of lithium is attracting attention in the field of LIBs. In the conversion reaction, the active electrode is consumed by Li ions and converted to an embedded nanometer-scale metal in a lithium-anion matrix. Conversion reaction materials have notable advantages, including high theoretical capacity because of transfer of more than one electron per 3D metal in a redox cycle. Good electronic conductivity from the Li$^-$X matrix (X = O, F, N, S, and P) and short diffusion distance from the metal nanocomposite are also benefits. However, conversion reaction materials have many drawbacks in terms of their use.

as negative electrode of LIBs. In particular, large polarization, irreversible capacity loss on first cycling, low Coulombic efficiency, extreme voltage hysteresis, volume expansion during the redox cycle, and poor kinetics have not yet been resolved.\textsuperscript{11−13}

Successful strategies to overcome these problems include reducing the particle size of materials to the nanometer scale to accommodate large volume change,\textsuperscript{8,13−18} and using amorphous electrodes to replace crystalline materials to achieve faster conversion reaction rates.\textsuperscript{19−24} Maier et al. reported enhanced potential of an amorphous RuO\textsubscript{2} electrode.\textsuperscript{20} Zachariah et al. reported that interspersed amorphous MnO\textsubscript{2}−carbon nanocomposites have superior electrochemical performance,\textsuperscript{19} and Stevenson et al. demonstrated a great method to produce amorphous FeP\textsubscript{2} in high yield and remarkable performance.\textsuperscript{21}

However, to the best of our knowledge, there is no report about pure difference between amorphous and crystalline electrodes except for other factors such as size differential, existence of conducting agent, different morphology, and so on. Our group has the curiosity for a pure amorphous effect on conversion reaction system under identical conditions.

Therefore, we are trying to introduce a facile method for synthesizing amorphous and crystalline dinickel phosphide nanoparticle clusters. Furthermore, the electrochemical difference of conversion reaction between crystalline and amorphous materials with Li\textsuperscript{+} by using nickel phosphides was analyzed. Synthetic methods for nanoscale Ni\textsubscript{2}P in different forms such as wires, solid particles, hollow particles, and rods were reported.\textsuperscript{25−28} Research studies about sandwich-like-coupled Ni\textsubscript{2}P nanoparticles and graphene were also studied.\textsuperscript{59,50} In particular, amorphous nickel phosphide was introduced by Tracy group that amorphous-solid nickel phosphate forms at 240 °C under phosphine-rich condition.\textsuperscript{31} In addition, Tu group made a core/shell-structured amorphous@crystalline nickel phosphate nanoparticles by ionothermal method.\textsuperscript{22}

Herein, a facile method to synthesize Ni\textsubscript{2}P nanostructures with controlled crystallinity and identical morphology by adjusting the quantity of nickel acetylacetonate is introduced. Furthermore, amorphous Ni\textsubscript{2}P (a-Ni\textsubscript{2}P) nanoparticle clusters were electrochemically compared with crystalline Ni\textsubscript{2}P (c-Ni\textsubscript{2}P) to unveil the amorphous effect on the conversion reaction with Li\textsuperscript{+}.

\section{2. RESULTS AND DISCUSSION}

Amorphous and crystalline Ni\textsubscript{2}P nanoparticle clusters with identical morphology were synthesized by the thermal decomposition of metal surfactant complex, depending on the nickel precursor concentration. To obtain the nanostructured Ni\textsubscript{2}P materials, we adopted the thermal decomposition method of metal−surfactant complex, which is superior to other synthetic routes in terms of control of size, morphology, and phase.\textsuperscript{25} Using this method, we successfully synthesized the Ni\textsubscript{2}P nanostructured anode materials with controlled morphology and crystallinity of Ni\textsubscript{2}P nanomaterials by facile control of molar concentration of injected precursors. Figure 1 shows the X-ray diffraction patterns for the resulting a-Ni\textsubscript{2}P, c-Ni\textsubscript{2}P, and self-assembled Ni\textsubscript{2}P (s-Ni\textsubscript{2}P) nanoparticle clusters, respectively. Figure 1a has only a broad peak at about 45°, indicating that an amorphous material was synthesized. Transmission electron microscopy (TEM), scanning electron microscopy (SEM), and energy-dispersive spectroscopy (EDS) measurements were performed to verify that the sample (a) is Ni\textsubscript{2}P. The X-ray diffractometer (XRD) patterns of c-Ni\textsubscript{2}P nanoparticle clusters (Figure 1b) and s-Ni\textsubscript{2}P nanoparticle clusters (Figure 1c) were perfectly matched with hexagonal nickel phosphide (JCPDS 74-1385). Broadening in the peaks of both particles implies the formation of nanometer scale particles. Furthermore, the diffraction peaks of s-Ni\textsubscript{2}P nanoparticle clusters were stronger and sharper than those of c-Ni\textsubscript{2}P nanoparticle clusters, indicating higher crystallinity.

Figure 2a,c shows TEM images of crystalline and amorphous Ni\textsubscript{2}P nanoparticles clusters. Figure 2b,d clearly demonstrates that two types of nanoparticles have similar spherical morphology and size. The corresponding electron diffraction patterns of a-Ni\textsubscript{2}P were smeared in one circle elucidating that the nanoparticles were amorphous (Figure S1). High-resolution TEM image of the c-Ni\textsubscript{2}P showed the lattice fringe with the lattice spacing of 0.22 nm, which is corresponding to the (111) planes of hexagonal Ni\textsubscript{2}P structure indicating the crystalline property (Figure S2). Each particle is on average 5 nm in diameter, and these small particles join together to form clusters. In addition, EDS measurements confirm that amorphous nanoparticle clusters are dinickel phosphides (Figure 2e). The ratio of components between nickel and phosphorus is almost 2:1. Cu and C come from the carbon-coated Cu substrate. Figure 3 illustrates the synthetic procedure. a-Ni\textsubscript{2}P and c-Ni\textsubscript{2}P electrodes that have identical morphology and size were prepared by injecting an Ni−trioctylphosphine (TOP) solution into TOP oxide (TOPO) as a bottom solution at 330 °C. The high temperature of the bottom solution leads to instantaneous formation of nuclei, followed by slow growth.\textsuperscript{33} As a result, Ni\textsubscript{2}P nanoparticles are formed. The synthetic mechanism of nickel phosphides is very well-known.\textsuperscript{25,26,34} Our group previously reported that TOP is a good phosphorus source precursor to synthesize transition-metal phosphides.\textsuperscript{26,55} Because C−P bonds in TOP catalytically are cleaved when combined with some metals, P atoms can diffuse into the metal,\textsuperscript{36} thereby generating metal phosphides. a-Ni\textsubscript{2}P, c-Ni\textsubscript{2}P, and s-Ni\textsubscript{2}P nanoparticle clusters are generated by adjusting the quantity of nickel acetylacetonate, which made it possible to limit the aging temperature. All syntheses are conducted under a TOP-rich condition in comparison with other experiments.\textsuperscript{25,31,57} because a TOP-rich
environment acts not only as a P source but also as a surfactant. When the volume of Ni–TOP solution is based on 10 mL, 0.357 M Ni–TOP solution limits the reaction temperature (~315 °C) by the high concentration of the nickel precursor, and c-Ni2P nanoparticle clusters are then generated. When the concentration of Ni–TOP solution is higher than 0.714 M, a-Ni2P nanoparticle clusters are formed because of the low reaction temperature (~290 °C) by the nickel precursor. Low aging temperature (below 300 °C) leads to amorphous Ni2P nanoparticles and a large amount of undecomposed TOP causes the nanoparticles to cluster.

Furthermore, a lower concentration (0.1 M) does not impose a temperature limitation, and hence high reaction temperature (330 °C) leads to the formation of s-Ni2P nanoparticle clusters (Figure 2e). From the result of low volume/high concentration experiments, the reaction temperature has a dominant effect on shape control of crystalline Ni2P over the injection solution concentration. The quantity of nickel precursor was fixed at 0.5 mmol, and the amount of TOP was reduced to 5, 2, and 1 mL. As the amount was decreased, the self-assembled spherical morphology collapsed (Figure S3).

2.1. Electrochemical Properties. Electrochemical measurements were performed on a 2016 coin-type half-cell, where Li metal foil was used as the counter electrode. Figure 4a shows the cycling performance of the Ni2P electrodes at 0.5 C, and Figure 4b describes the rate performance of the Ni2P electrodes. The first discharge capacities of a-Ni2P and c-Ni2P electrodes were 942.6 and 974.9 mA h g⁻¹, and the reversible charge capacities were 573.2 and 526.8 mA h g⁻¹, respectively. The higher capacities over the theoretical capacity (542 mA h g⁻¹) in the first cycle are related to decomposition of the electrolyte upon reduction with the formation of a polymeric film at low potentials and interfacial storage of Li⁺. Additionally, the a-Ni2P electrodes exhibited better cycle result compared to c-Ni2P electrodes. This result means that the isotropic environment and the absence of grain boundaries of amorphous structure relieve the damage during the insertion of lithium ion. In the subsequent cycles, the a-Ni2P electrode showed better Coulombic efficiency (99.1%) and capacity retention than the c-Ni2P electrode (96.8%). Furthermore, reversible capacities of the two forms of Ni2P after 50 cycles were 351.5 and 262.9 mA h g⁻¹. In Figure 4b, the rate performance of a-Ni2P nanoparticles is higher than c-Ni2P, and it means that diffusion of lithium ion in a-Ni2P nanoparticles is superior to c-Ni2P. According to previous studies, it has been suggested that percolation pathways from interfacial region in disordered structure increase the Li diffusivity. The reason for enhancement is an increase of pre-exponential factors and/or a decrease of the activation energy of the Arrhenius equation. One of the products, s-Ni2P nanoclusters, was also

Figure 3. Schematic illustration of the formation of nickel phosphides.
studied because it is well-established that self-assembled structures have the potential to reduce the transport pathways of Li+ ions and electrons. To confirm the effect of secondary hierarchical Ni2P structures, we evaluated its cycle performance and electrochemical impedance spectroscopy (EIS) measurement (Figure S4). However, its specific capacity (174 mA h g−1 after 30 cycles) was significantly lower than the theoretical capacity (542 mA h g−1); we thought that significant side reactions would be dominant in this case compared to a-Ni2P and c-Ni2P nanoparticles. The cell performance of a-Ni2P nanoparticles (351.5 mA h g−1) can be matched with other type of Ni2P electrodes. Porous Ni2P nanosheets, single crystalline Ni2P nanowires, and hierarchical Ni2P spheres presented the reversible capacities of 379.8, 326, and 365.3 mA h g−1 respectively at 0.5 C after 50 cycles. Comparing to the amorphous anode electrode, the performance of c-Ni2P (262.9 mA h g−1) was significantly lower than other structured Ni2P electrodes.

The gap in the initial reversible capacity was continuously maintained throughout the cycling. In other words, the initial Coulombic efficiency (ICE) is very important in conversion reaction electrodes. The gap in the ICE between the two nickel phosphide electrodes proves that a-Ni2P is superior to c-Ni2P at the first cycle. The a-Ni2P nanoparticle cluster electrode has a higher ICE (average 63.61%) than the c-Ni2P nanoparticle cluster electrode (average 58.20%) at 0.1 C, and the same results were obtained at 0.5 C (Figure S5). The irreversible capacity loss upon the first cycle is from the formation of a solid electrolyte interphase (SEI) layer and irreversible conversion reaction. To shed light on this irreversible capacity gap of both electrodes upon first cycling, we analyze both electrodes by the galvanostatic intermittent titration technique (GITT). The GITT is one of the most powerful techniques for obtaining key thermodynamics and kinetic data about battery performance. Figure 5a shows the GITT curves of the two electrodes. The relaxation time is 4 h. It is well-known that upon first cycling, nickel phosphides convert to Li3P and Ni with an intermediate step of an insertion reaction. In the initial normalized capacity region, the plateau indicates that Ni2P forms intermediate Li−Ni2P insertion reaction because of the covalence of nickel phosphides. Another plateau represents the conversion process where Li−Ni2P and lithium convert to a Li3P matrix and nickel metal. The advantage of a-Ni2P in electrical networking was confirmed by EIS measurements (Figure 5b). By comparing the result of c-Ni2P electrodes, the spectra for a-Ni2P electrodes exhibit much smaller high-frequency semicircle which is interpreted by enhanced electronic conductivity and charge-transfer kinetics of the a-Ni2P networking. The polarization between closed-circuit voltage and quasi-open-circuit voltage (QOCV) after 4 h relaxation at the first cycling is indicated in Figure S6. In the initial discharge region, polarization of a-Ni2P was higher than that of c-Ni2P. However, the polarization reversed during the

Figure 5. (a) GITT curves of both electrodes in the first cycle and (b) Nyquist plots for electrodes of a-Ni2P nanoparticles and c-Ni2P nanoparticles.
The volume expansion of electrodes during lithiation and delithiation was measured through ex situ measurement of electrode thickness change (Figure 6). All cells were cycled for 0.1 C at 30 °C in a potential range of 0.02–3.0 V versus Li/Li'. After full lithiation until the redox potential of the working electrode reached 0.02 V versus Li/Li', the c-Ni2P and a-Ni2P electrodes led to considerably smaller volume expansion than the theoretical volume expansion because the nanostructure reduces the mechanical strain induced by volume change. In addition, the a-Ni2P electrode showed considerable volume expansion of about 120%, whereas the c-Ni2P electrode displayed a thickness change of about 164% in the fully lithiated state. As shown in SEM data (Figure S8), we could detect more heterogeneous region on c-Ni2P electrodes compared with a-Ni2P electrodes. A tendency to agglomerate between s-Ni2P nanoclusters after cycling in SEM image was observed because high crystallinity is unfavorable to relieve the damage during insertion of lithium ion (Figure S9). As the cycle processed, the contact between c-Ni2P and binder was rapidly deteriorated, and this might interrupt the migration of electrons in electrodes.

Figure S10 shows the electrochemical behavior of the a-Ni2P and c-Ni2P nanoparticle cluster electrodes characterized by cyclic voltammograms at a scanning rate of 0.2 mV s−1 between 0.02 and 3 V. The small anodic peak of a-Ni2P at 1.80 V implies that Ni2P reacts with Li+ by an insertion process. The maximum reduction peak of a-Ni2P at 0.66 V. The maximum peak indicates that Li+−Ni2P decomposes to not only metallic Ni and a Li3P matrix but also forms of the SEI layer. For c-Ni2P, these peaks shift to 1.93 and 0.94 V. Comparing the intensity of redox peaks of both electrodes, the peaks of the a-Ni2P electrode are sharper than those of c-Ni2P. In particular, the second oxidation peak of the a-Ni2P electrode, which is evidently higher than the others, suggests that the amount of reversible reaction is larger than that of the c-Ni2P electrode.

3. CONCLUSIONS

Crystalline and amorphous nickel diphosphide nanoparticle clusters that have almost same shape and size were synthesized by a simple hot-injection method. This was achieved by adjusting the quantity of nickel acetylacetonate, which made it possible to limit the aging temperature. Furthermore, its electrochemical characteristics were investigated to analyze the effect of amorphous morphology on the conversion reaction in a LIB. These materials were characterized by TEM, SEM, XRD, and EDS. From the characterization, amorphous and crystalline spherical ~5 nm clusters have almost the same size and structure. In addition, self-assembled Ni2P nanoparticle clusters could be generated at 330 °C without oleylamine. The electrochemical results showed that amorphous materials in isolation from other factors can be used to overcome the problems impeding conversion reaction materials, such as low...
ICE, large voltage hysteresis, capacity retention, and serious volume expansion. a-Ni2P provides superior ICE over the crystalline materials in the conversion reaction with Li′ because there is no amorphization process. In addition, amorphous nickel phosphate can reduce voltage hysteresis and volume expansion during cycling, which are very serious obstacles to the commercialization of conversion materials. In the future, it will be of significant interest to synthesize amorphous nanometer scale conversion materials such as iron oxides and manganese oxides.

4. EXPERIMENTAL SECTION

4.1. Materials. Nickel(II) acetylacetonate anhydrous [Ni(acac)2] 95% was purchased from Strem Chemical Inc. Chloroform, technical grade, 90% and TOP, technical grade, 90% were purchased from Sigma-Aldrich Co. LLC. Chloroform and ethanol were purchased from SK Chemical. All chemicals were used without further purification.

4.2. Synthesis of Nanosized Ni2P Particles. The Ni2P materials were synthesized by a hot-injection method in an argon atmosphere using standard Schlenk-line techniques. The s-Ni2P was prepared by the following procedure. A Ni–TOP solution was prepared by reacting 1 mmol of Ni(acac)2 and 10 mL of TOP (0.1 M Ni–TOP) at 60 °C until the solution became sky blue. A TOPO solution was also prepared by vigorous stirring at 330 °C. The Ni–TOP solution was added to 5 g of TOPO solution at once, and then the complex solution was maintained for 30 min. The reaction was stopped by cooling to room temperature. The nanoparticles were isolated by the addition of 30 mL of ethanol and 5 mL of chloroform and ethanol were purchased from SK Chemical. All chemicals were used without further purification.

4.3. Characterization. Powder XRD data were collected on a D/MAZX 2500V/PC (Rigaku) using Cu Kα radiation (λ = 0.15405 nm), operated for 2θ = 10–80° with a scan rate = 2°/min. The material morphology was examined using a field-emission TEM (JEOL JEM-2100) operated at 200 kV and a cold field-emission SEM (Hitachi s-4800). After cycling, cells were disassembled at an atmosphere environment to observe changes of thickness of electrodes. The electrodes were washed several times with dimethyl carbonate (DMC) to remove electrolyte and dried for ex situ measurement. The thickness of five randomly selected points of dried electrodes was measured by Vernier calipers.32 This ex situ measurement was proved to be an efficient way to estimate the change of volume, easily verifying the volume change behavior. For ex situ SEM, the cells were disassembled after 23 cycles in Ar-filled glovebox and then washed by DMC.

4.4. Electrochemical Investigation. Electrochemical measurements were performed on a 2016 coin-type half cell, where Li metal foil was used as the counter electrode. The working electrodes were fabricated using a mixture of active materials (75 wt %), super P (15 wt %), and polyvinylidene fluoride binder (LG Chem. 10%) in N-methylpyrrolidinone. The electrolyte was 1.3 M LiPF6 in a 3:7 volume mixture of ethylene carbonate and diethyl carbonate, and a microporous polyethylene film was used as a separator. The weight of the anode materials was measured as ~0.9 mg for each cell. Cells were assembled in an Ar-filled glovebox with less than 1 ppm of both oxygen and moisture. Galvanostatic charge and discharge cycling (WonA Tech WBCS 3000 battery measurement system) was performed in a potential window from 0.02 to 3.0 V versus Li/Li′ at current densities from 0.1 to 5 C. The EIS was measured from 1.5 MHz to 5 mHz with an amplitude of 10 mV. The half-cells were discharged to 0.4 V (vs Li/Li′) at 270 mA g\(^{-1}\), and a constant voltage of 0.4 V was applied until the current decreased to 27 mA g\(^{-1}\). Then, the cells were allowed to rest for 3 h. Cyclic voltammograms were performed at a scanning rate of 0.2 mV s\(^{-1}\) between 0.02 and 3 V using an SP150 potentiostat (BioLogic Science Instruments) with homemade three-electrode cells.
