We present high-contrast electromagnetically-induced-transparency (EIT) spectra in a heated vapor cell of single isotope $^{87}$Rb atoms. The EIT spectrum has both high resonant transmission up to 67% and narrow linewidth of 1.1 MHz. We get rid of the possible amplification resulted from the effects of amplification without population inversion and four-wave mixing. Therefore, this high transmitted light is not artificial. The theoretical prediction of the probe transmission agrees well with the data and the experimental parameters can be derived reasonably from the model. Such narrow and high-contrast spectral profile can be employed as a high precision bandpass filter, which provides a significant advantage in terms of stability and tunability. The central frequency tuning range of the filter is larger than 100 MHz with out-of-band blocking $\geq 15$ dB. This bandpass filter can effectively produce light fields with subnatural linewidth. Nonlinearity associating with the narrow-linewidth and high-contrast EIT profile can be very useful in the applications utilizing the EIT effect.

A high-contrast electromagnetically-induced-transparency (EIT) medium can be realized as an atomic high-precision bandpass filter$^{1-3}$. This filter can effectively produce a narrow-bandwidth light field and precisely tune the light frequency by selecting the atomic transition. Therefore, it is very valuable in the preparation of photon sources for possible future applications in quantum information processing$^{6,7}$. In practical applications utilizing EIT-based nonlinear optical responses, recently, an increasing number of researches have turned to the study in warm atomic media$^{8-12}$. Such systems reduce the complexity of experimental setup and increase the repetition rate of quantum devices. An earlier study obtained an ultranarrow EIT linewidth in an anti-relaxation-coated cell in order to reduce the ground-state decoherence rate$^{13}$. Very recently, near-unity EIT transmission efficiency has been reported in the microwave regime$^{14}$. However, an EIT spectrum simultaneously satisfying the condition of narrow linewidth, high peak transmission, and low baseline transmission has not been presented to the best of our knowledge. Here, we report a high-contrast spectrum with subnatural linewidth of 1.1 MHz, EIT peak transmission of up to 67%, and the baseline transmission as low as 3%. Such excellent EIT characteristics advance the realization of optical memory using slow light.

An EIT spectrum can predict the features of optical memory or photon sources. The probe field propagating in the EIT medium induces a dramatically spatial compression, accompanied with ultraslow group velocity. The light field is possible to be stored in the medium as an optical memory$^{15}$. Storage of light in an atomic vapor has been experimentally accomplished in 2001 with storage time of up to 0.5 ms in a magnetically-shielded and buffer-gas-filled cell$^9$. This work was then extended into the quantum regime of single photons$^{10,17}$. The efficiency for the storage and retrieval of light pulses can be optimized by applying time-reversal procedure in a low optical density system$^{18,19}$. In addition, for the research of biphoton generation in an EIT-based spontaneous four-wave-mixing (SFWM) process$^{20-23}$, the EIT linewidth and peak transmission correspond to the bandwidth and generation rate of the single-photon sources, respectively. The generated photon is engineered to match the wavelength and the bandwidth of the atomic transition, and it would be a perfect information carrier which well fits the requirements for the EIT-based optical memory$^{24}$. These researches pave the avenue for the realization of quantum devices in Doppler-broadening media.

The characterizations of a high-performance EIT-based memory are the long delay time and high transmission of slow-light pulse. The optical density of the system (OD, denoted as $\alpha$) is determined by the resonant probe field transmission. We can estimate the optical delay time from the EIT linewidth (W) and optical density, which is proportional to $\alpha W$ under the perturbation limit for Doppler-free media$^{25}$. The EIT resonant transmission is another factor to determine the optical memory efficiency. We will provide a theoretical model by considering...
with ultranarrow bandwidth, flexible central frequency, high peak transmission, and high out-of-band extinction. A high-precision spectrum, a tiny frequency shift of 30 kHz is resolvable. Therefore, we demonstrate an optical filter whose central frequency tuning range of the filter is larger than 100 MHz by varying the coupling field transition frequency and the out-of-band profile can be employed as a pre-filter of single-photon sources from other systems. The central frequency tuning of EIT spectra.

Results and Discussion

EIT spectra. We perform a continuous-wave EIT spectrum study in a $^{87}$Rb-filled cell. With the help of a coupling field and a Zeeman pumping field, all populations accumulate at two Zeeman ground states $|1\rangle$ and $|F = 1, m_F = 1\rangle$, as shown in Fig. 1. The probe field and the coupling field drive the transitions from the ground states $|1\rangle$ and $|2\rangle$ to the same excited state $|3\rangle$, respectively, forming a $\Lambda$ configuration of EIT. In each EIT spectrum measurement, we frequency lock the coupling laser and sweep the probe laser frequency via electro-optic modulation. Further details of data analysis can be found in Methods. In the absence of the Zeeman pumping beam, the populations are distributed among different degenerate Zeeman states of hyperfine level $F = 2$ and state $|F = 1, m_F = 1\rangle$, decreasing the optical density. Therefore, the spectrum has a higher floor level as shown in Fig. 2(a). In addition, the population in the state $|F = 2, m_F = 0\rangle$ does not participate in the EIT transition because of the absence of the corresponding coupling field transition. Instead, the atoms contribute to the absorption of the probe field at the resonant frequency, resulting in a lower EIT transmission.

With a sufficiently strong Zeeman pumping field, the population accumulates at two Zeeman dark states. Both the optical density and EIT peak height (defined as the difference between the transmissions of EIT peak and baseline) increase and become saturated when the power of the Zeeman pumping field is stronger than 5 mW. In the whole measurements, a power of 14 mW is applied. We obtain an EIT peak transmission as high as 67% and a full width at half maximum of EIT linewidth of 1.1 MHz, shown in Fig. 2(b). It is worth noting that the low baseline transmission of only 3% lasted over 100 MHz, implying a large optical density. Such excellent EIT spectral extinction is larger than 15 dB. In addition, the EIT peak frequency linearly shifts with varied coupling field power, as shown in Fig. 2(c,d). This can be explained by the AC Stark effect (see Methods). As the result of the high-precision spectrum, a tiny frequency shift of 30 kHz is resolvable. Therefore, we demonstrate an optical filter with ultranarrow bandwidth, flexible central frequency, high peak transmission, and high out-of-band extinction.

The model. In order to gain more insight into the EIT spectrum, we provide a theoretical analysis by solving the optical Bloch equations (OBEs) and Maxwell-Schrödinger equation (MSE) under the perturbation limit (i.e. the Rabi frequency of the probe field $\Omega_p$ is much weaker than that of the coupling field $\Omega_c$). The outgoing probe field is derived from the thermally-averaged atomic coherence of $\rho_{31}^{(v)}$. For a group with velocity $v = v^2$ relative to the laboratory frame, the dynamics of atomic coherences in the atomic frame are written as the follows.

$$
\frac{\partial \rho_{21}^{(v)}}{\partial t} = \frac{i}{2} \Omega^*_{pp} \rho_{31}^{(v)} + i\Delta'_{p} - i\Delta_{p} \rho_{21}^{(v)},
$$

(1a)

$$
\frac{\partial \rho_{31}^{(v)}}{\partial t} = \frac{i}{2} \Omega^*_{pp} \rho_{21}^{(v)} + \frac{i}{2} \Omega_p - \frac{\Gamma}{2} - i\Delta'_{p} \rho_{31}^{(v)},
$$

(1b)
Here $\rho_{ij}$ is an element of the density-matrix operator in an EIT system, $\gamma$ denotes the ground state decoherence rate, $\Gamma$ is the spontaneous decay rate of the excited state which is $2\pi \times 5.75$ MHz for Rb $D_1$-line transition, $c$ is the speed of light in vacuum, and $L$ is the length of the medium. The physical definition of $\alpha$ here represents the optical density resulting from the entire ensemble having the resonant absorption cross section, and it can be directly derived from the system condition $n_\sigma L$, where $n$ is the atomic density and $\sigma$ is the absorption cross section. For a given temperature $T_c$, atomic velocities are described by the Maxwell-Boltzmann distribution, $f(v) = \exp[-\frac{mv^2}{2k_B}]$, where $m$ is the atomic mass and $k_B$ is the Boltzmann constant. The atomic motion induces Doppler shifts, $\Delta p' = \omega_{31} - \omega_p - k_pv$ and $\Delta c' = \omega_{32} - \omega_c - k_cv$, where $\omega_{ij}$ denotes the transition frequency between the energy levels $|i\rangle$ and $|j\rangle$ and $\omega_{cp}(v)$ is the probe (coupling) laser frequency. Because $k_p \simeq k_c$, $\Delta p' - \Delta c'$ is replaced by $\Delta_p - \Delta_c \equiv \delta$, defined as two-photon detuning. In our measurements, $\Delta_c = 0$ because of frequency locking.

Additionally, we consider the optical pumping effect that causes the atomic accumulation for different velocity groups. Strong Zeeman pumping and coupling fields pump more high-velocity groups to the ground state $|1\rangle$ with detunings of $\Delta_p' \simeq k_v \gg \Gamma$ (in the atomic frame). These high velocity groups then participate the EIT peak transition (around $\Delta_p = 0$ and $\delta = 0$) with large one-photon detunings $\Delta_p \equiv k_v$, meanwhile at out-of-band detunings of $\Delta_c \gg \Gamma$ these velocity groups absorb the resonant probe field (because of $\Delta_c = 0$), resulting in a broader absorption spectrum. The selection of velocity groups is expressed as the power broadening function, $g(v) = \frac{1}{1 + 4(k_v)^2/\Gamma^2}$.

The optical pumping linewidth $\Gamma_{OP}$ is nearly a linearly increasing function of the powers of the Zeeman pumping and coupling fields. In all of the measurements, the values of $\Gamma_{OP}$ varied from 18 to 120 according to different laser intensities.

Based on the steady-state solution of the optical-Bloch equations, we derive $\rho_{31}^{(v)}$ from Eq. (1a) and (1b),

$$\rho_{31}^{(v)} = \frac{2i(\gamma - i\Delta_p)}{[\Omega_p^2 + 2(\gamma - i\Delta_p)[\Gamma - 2i(\Delta_p - k_p)v]]} \equiv \sigma(v, \Delta_p).$$

The probe transmission is a function of the probe field detuning by inserting $\rho_{31}^{(v)}$ into Eq. (1c),

$$\rho_{31}^{(v)} = \frac{i\Gamma}{2L} \int \frac{df(v)\rho_{31}^{(v)}(v)dv}{df(v)}.$$
Figure 3. The calibration factor $C_\alpha$ for a Doppler-broadened medium is a function of optical pumping linewidth $\Gamma_{OP}$ and EIT linewidth $\Gamma_{EIT}$. The EIT peak transmission $T(0) = \exp[-(2\alpha\gamma/\Gamma_{EIT}^2)C_\alpha]$ with the effective OD of $\alpha C_\alpha$. The six EIT spectra in Fig. 2(c) are also shown here with the corresponding $\Gamma_{OP}/\Gamma_D$ and $\Gamma_{EIT}/\Gamma_D$.

\[
T(\Delta_p) = \exp\left[-\alpha^2 \int \frac{\Gamma_{OP}}{2\pi \Gamma_D} \frac{2\gamma}{\Omega^2_c} + \frac{4\Delta_p^2 \Gamma_{OP}^2}{\Omega^4_c} \int e^{-\frac{x^2}{\Gamma_{EIT}^2}} \frac{1}{1 + \frac{4x^2}{\Gamma_{OP}^2} + \frac{4x^2}{\Gamma_{EIT}^2}} \, dx \right],
\]

where $\Gamma_D = \sqrt{2k_B T \hbar^2 / m} = 54\Gamma$ for the cell temperature of 42 °C.

To fit the spectrum by the model, we first determine the optical density $\alpha$ and optical pumping linewidth $\Gamma_{OP}$ from the baseline curve of the spectrum in a frequency range over ±50 MHz. The optical density $\alpha$ dominates the absorption depth and $\Gamma_{OP}$ individually governs the curvature of absorption line. From the systematic study, a stronger $\Omega_{p}$ corresponds to a larger $\Gamma_{OP}$ while the optical density remains nearly a constant. We consider 4001 velocity classes ranging from −200Γ to 200Γ. With the given $\alpha$ and $\Gamma_{OP}$, the best fit of the measurement in the stronger $\Omega_{p}$ takes place. With the given $\alpha$ and $\Gamma_{OP}$, the determined $\Gamma_{EIT}$ is modeled by

\[
\Gamma_{EIT} = \Gamma_{OP} \frac{\alpha \gamma}{\Gamma_{OP}} \Gamma_{EIT} = \Gamma_{OP} \frac{\alpha \gamma}{\Gamma_{OP}},
\]

where $\Gamma_{EIT}$ is defined as $\Omega^2_c/2\gamma$ and $k_p \nu$ is replaced by $x$ in unit of $\Gamma$. The EIT peak transmission can be written as

\[
T(0) = \exp\left[-2\alpha^2 \gamma (\Gamma_{OP}^2)^{-1} \right], \quad \text{where} \quad C_\alpha(\Gamma_{OP}, \Gamma_{EIT}) = \frac{1}{2\pi \Gamma_D} \int e^{-\frac{x^2}{\Gamma_{EIT}^2}} \frac{1}{1 + \frac{4x^2}{\Gamma_{OP}^2} + \frac{4x^2}{\Gamma_{EIT}^2}} \, dx.
\]

As mentioned before, the peak transition ($\Delta_p = 0$) is contributed by all of velocity groups which mediate one-photon-detuning EIT transition. The physical definition of $\Gamma_{EIT}$ here represents the linewidth in a velocity spectrum or one-photon-detuning spectrum. The EIT peak $T(0)$ in a Doppler-broadened medium has the similar expression $\exp[-2\alpha^2 \gamma/\Gamma_{EIT}^2]$ (which has been widely used in a Doppler-free ensemble) with a calibration factor $C_\alpha$. The finite EIT linewidth and optical pumping linewidth degrade the effective optical density. The calibration factor $C_\alpha$ as a function of $\Gamma_{OP}$ and $\Gamma_{EIT}$ is plotted in Fig. 3. Take the parameters of Fig. 2 for example ($\Gamma_{OP}/\Gamma = 90$ and $\Gamma_{EIT}/\Gamma = 400$), we derive $C_\alpha = 0.69$, which means the effective optical density of the EIT transmission $\alpha C_\alpha = 157$. We further discuss the propagation velocity of the probe pulse in this optically thick media. The phase of the probe field $\phi$ is expressed as

\[
\phi = \frac{-\alpha \gamma}{2\pi \Gamma_D} \int f(\nu) \operatorname{Re}[\sigma(\nu, \Delta_p)] g(\nu) \, k_p \, d\nu.
\]

We derive the group delay time of the slow-light pulse as $\alpha C_\alpha \Gamma / \Omega^2_c$ from $d\phi/d\Delta_p$ at $\Delta_p = 0$. The expression is similar to the one widely used in cold ensembles\(^{25}\). For a Doppler-free medium, the optical pumping linewidth
and EIT linewidth are both sufficiently broader than $\Gamma_D$. Thus, $C_c$ reaches unity. All of the populations are prepared to the dark states and then participate the EIT transition. On the other hand, if the linewidths are both sufficiently narrow, the effective optical density is only contributed from the Doppler-free atoms. The values of the above-mentioned linewidths provide the useful information on the range of velocity groups which need to be taken into account on the EIT transition. This model advances the knowledge in the thermal-EIT study.

Properties of EIT spectra. The expression of EIT peak transmission shows that a stronger coupling field leads to a higher transmission. We systematically study the EIT transmission with varied coupling field power. At each condition, the baseline transmission keeps at the same low level, indicating the optical density does not vary with $\Omega_c$. As $\Omega_c$ gets stronger, corresponding to larger $\Gamma_{op}$ and $\Gamma_{EIT}$, the EIT peak height and linewidth become higher and broader. The EIT peak transmission (circles) and linewidth (squares) with varied $\Omega_c$ are shown in Fig. 4(a,b). We further increased $\Omega_c$ by reducing the coupling beam size to 2.0 mm. The results are shown in Fig. 4(c,d). The EIT peak saturates at 70%. Further increasing $\Omega_c$ does not enhance the peak transmission but it does broaden the EIT linewidth. For the applications in optical filters or in biphoton generations via SFWM process\(^{20-23}\), the bandwidth of the filter or the linewidth of photon source is controllable while the central frequency maintains a high transmission.

The theoretical predictions with fixed optical density $\alpha = 225$ and decoherence rate $\gamma = 0.022\Gamma$ well fit the data of EIT peak transmission and linewidth, as the shown red curves in Fig. 4. At strong $\Omega_c$ regime, the peak height goes lower than the predicted value. The discrepancy is caused by the impurity of the coupling field polarization due to the photon switching effect\(^{26}\). The $\sigma^-$ coupling field destroys the quantum interference of EIT and thereby results in absorption of the probe field. In addition, the peak height at a weak $\Omega_c$ condition is also lower than the prediction because of the EIT transient effect. A weak $\Omega_c$ leads to a long EIT response time\(^{27}\). As the result of the finite atomic transient time that atoms move in and out of the interaction regime, EIT has not reached the steady-state condition, implying the degradation of the EIT peak height. Thus, the theoretical prediction supports the experimental observations and physical picture.

Moreover, for the purpose of photon source generation, we should get rid of any amplification. Once the beam size of the coupling field is too small, the population transient effect needs to be taken into account: The fresh atoms, entering the probe interaction region, is not optically pumped to the Zeeman dark states in advance, and therefore, the probe field is amplified through the so-called amplification without population inversion (AWI)\(^ {28}\). A smaller coupling beam size can potentially make the AWI more prominent. At the same value of $\Omega_c$, the peak transmission of the coupling beam size of 2.8 mm shown in Fig. 4(a) is less than that of 2.0 mm shown in Fig. 4(b) by less than 2.5%. The amplification due to the AWI effect is very insignificant in the data of 67% peak transmission shown in Figs 2(b) and 4(a). Furthermore, the four-wave-mixing (FWM) amplification, in which the coupling field also excites the population in the ground state driven by the probe field\(^ {29}\), is not allowed in our experiment. This is because the coupling and probe fields need to have the same polarization to induce this amplification, but they have the orthogonal-polarization configuration here. We further exclude the amplification induced by a little impurity of the $\sigma^-$ polarization of Zeeman pumping field via another kind of FWM process\(^ {20-23}\). When the atomic transitions involve any gain effect, the determined decoherence rate $\gamma$ should go lower. To test whether there could be any gain effect, we adjust the polarization ratio of $\sigma^-$ to $\sigma^+$ components of the Zeeman pumping field, whose Rabi frequencies are denoted as $\Omega_{zp}$ and $\Omega_{zp}'$, respectively. When the ratio $(\Omega_{zp}/\Omega_{zp}')^2 < 0.03$, $\gamma$ did not change; and once the

![Figure 4](https://example.com/figure4.png)

**Figure 4.** EIT peak transmission and linewidth with varied coupling field power. The beam size ratios of the coupling and probe fields are 4.0 (in (a) and (b)) and 2.8 (in (c) and (d)). The prediction curves, shown in red, are calculated by Eq. (3) under fixed parameters of $\alpha = 225$ and $\gamma = 0.022\Gamma$. $\Omega_c$ and $\Gamma_{op}$ are determined by the measured spectra and both are nearly linear functions of the coupling power.
ratio became 0.06, $\gamma$ increased by 6%. Since $(\Omega_{2p}^\uparrow/\Omega_{2p}^\downarrow)^2$ in our system is less than 0.01, the FWM gain does not occur in our system. Hence, we believe the high EIT transmission is not artificial and such a high-contrast EIT spectrum would be useful in the future applications.

Conclusion

We systematically investigate the thermal-EIT spectra which can make a quality prediction for a slow light or photon source. The spectral profile shows a high EIT peak transmission of 67%, a narrow EIT linewidth of 1.1 MHz, and a low off-resonant transmission less than 3%. We get rid of the possible amplification, and hence this high transmitted light is not artificial. A high-contrast EIT medium can be applied as an ultranarrow-bandwidth filter. The central frequency of the filter can be precisely tuned, making it flexible in the generation of photon sources with subnatural linewidth. We further provide a theoretical model to simulate EIT spectra. The prediction fits the data well and the experimental parameters can be reasonably derived from the model. Hence, the spectral measurements and theoretical model advance our knowledge in the thermal-EIT study.

Methods

**Setup and Measurements.** We perform a continuous-wave EIT spectrum study in a $^{87}$Rb-filled cell (Thorlabs GC25075-RB). All of the laser fields drive $D_2$-line transition at wavelength of 795 nm. With the help of the coupling field (which couples the transition between states $|F = 1\rangle$ and $|F = 1\rangle$ and the Zeeman pumping field (which couples that between states $|F = 2\rangle$ and $|F = 2\rangle$), all populations accumulate at two Zeeman ground states $|1\rangle$ and $|F = 1\rangle$, as shown in Fig. 1. The coupling field is produced by an external cavity diode laser (ECDL). One beam from the ECDL is sent through an electro-optic modulator (EOM) before injection locking the probe field. The probe and coupling beams are nearly collinear propagating to reduce two-photon Doppler shift for the spectrum in Fig. 2(b) is only 20% different from the estimated value of $(\gamma/\Omega)^2/4\Delta_{AC}$.

Data Analysis. For each EIT spectrum, we normalize the probe transmission by the incident power. In the absence of the coupling field, 0.6% of the probe field can be no longer absorbed at a further larger optical density medium by heating up the cell temperature. This component came from the sideband signal of the probe laser, which was injection-locked by the coupling laser after an EOM. It has to be subtracted for the calculation of the probe field transmission. The incident power of the probe field was measured at a far-off-resonant frequency (6.8-GHz red-detuned respectively with the resonant transition of $|1\rangle$ to $|3\rangle$). The applied power of the probe field was typically 2.4 $\mu$W right before the cell and the maximum power of the coupling beam was 10 mW.

AC Stark Shifts. As shown in Fig. 2(c,d), the central frequency of EIT peak linear shifts with the applied coupling field power due to the AC Stark effect. The coupling field also couples the far-off-resonant transition between states $|F = 2\rangle$ with detuning of 814.5 MHz. We suppose that the velocity group of $v = 0$ dominates the transition so that $\Delta_{AC} = 814.5$ MHz is not a velocity-dependent function. We further assume that the coupling field only drove one far-off-resonant transition from state $|2\rangle$ to state $|F = 2, m_F = 1\rangle$. The transition has a Clebsch–Gordan coefficient that is $\sqrt{3}$ times as lager as that of $|2\rangle$ to $|3\rangle$ transition. The amount of AC Stark shift for the spectrum in Fig. 2(b) is only 20% different from the estimated value of $(\gamma/\Omega)^2/4\Delta_{AC}$.

Acknowledgements
This work received the support of the Ministry of Science and Technology of Taiwan under Grant Nos. 106-2119-M-007-003 and 105-2112-M-007-035-MY2.

Author Contributions
G.W. and I.A.Y. conceived the study and designed the experiment. G.W., Y.-S.W., E.K.H., W.H., K.-L.C. and P.-Y.W. carried out the experiment supervised by I.A.Y. Y.-H.C. and I.A.Y. analyzed the data. Y.-H.C. wrote the manuscript with the help from Y.-S.W., E.K.H. and I.A.Y.
