(Dated: May 10, 2014)

The superconducting compound, LiFeAs, is studied by scanning tunneling microscopy and spectroscopy. A gap map of the unreconstructed surface indicates a high degree of homogeneity in this system. Spectra at 2 K show two nodeless superconducting gaps with $\Delta_1 = 5.3 \pm 0.1$ meV and $\Delta_2 = 2.5 \pm 0.2$ meV. The gaps close as the temperature is increased to the bulk $T_c$ indicating that the surface accurately represents the bulk. A dip-hump structure is observed below $T_c$ with an energy scale consistent with a magnetic resonance recently reported by inelastic neutron scattering.

PACS numbers: 74.55.+v, 74.20.Mn, 74.20.Rp, 74.70.Xa

In the new family of high temperature superconductors, the iron pnictides, a general consensus is emerging in favor of an $s_{\pm}$ symmetry although other pairing states such as p-wave [4, 5] and d-wave have also been suggested [2, 3]. A challenge in unambiguously identifying the pairing state in this class of materials is that experimental investigations are occurring against a backdrop of variations in sample purity and quality. In particular many of these compounds have intrinsic limitations due to high defect density from cation doping in the bulk, or structural or electronic reconstructions which complicate surface sensitive investigations [6, 7].

A particularly interesting compound among the pnictides is LiFeAs which is superconducting without cation substitution [8, 9]. This potentially places it in the same position that YBa$_2$Cu$_3$O$_{7-x}$ (YBCO) holds in the cuprates [10], a stoichiometric superconductor that can be chemically and structurally perfect enough to avoid artifacts arising from disorder. LiFeAs has the additional advantage of a natural cleaving plane, exposing a non-polar surface that does not undergo reconstruction [11], making it well suited to surface sensitive spectroscopic studies such as angle resolved photoemission spectroscopy (ARPES) [12, 13] and scanning tunneling microscopy and spectroscopy (STM and STS) [14, 15], much like the cuprate Bi$_2$Sr$_2$CaCu$_2$O$_{8+x}$ (BSCCO) [17, 18].

In this letter, we show through STM that the surface is clean and unreconstructed. Through spatially resolved STS measurements, we find that the gap structure is extremely homogeneous, presenting an opportunity to study a clean and well-defined system. STS acquired at 2K reveal two nodeless gaps, consistent with a multiband $s_{\pm}$ pairing state [1]. We find that the temperature dependence of the gap is BCS-like, in contrast to the fluctuation driven transition [19] and pseudogap phase present above $T_c$ in the cuprates [20]. All of these simplifying features offer a system in which to study a feature LiFeAs does have in common with the cuprates; a pronounced structure above the superconducting gap, indicating strong coupling to boson modes.

FIG. 1. (a) $80 \times 80 \text{ nm}^2$ scanning tunneling topographic image of LiFeAs ($V_B=50 \text{ mV}, I_T=20 \text{ pA}$) at $T=4.2$K and (b) $6.8 \times 6.8 \text{ nm}^2$ atomic resolution topographic image of LiFeAs ($V_B=40 \text{ mV}, I_T=100 \text{ pA}$). (c) Schematic of the crystal structure from the cleaved (001) direction and an edge-on view. (d) d$I$/d$V$ spectrum in a range from -550 mV to +550 mV.

Single crystals of LiFeAs were grown by a self-flux technique. Li$_3$As and FeAs, pre-synthesized from Li (99.9%), Fe (99.995%) and As (99.999%), were mixed in a composition of 1:2 and sealed under 0.3 atm Ar. The mixture was heated to 1323 K for 10 hours, then cooled to 1073 K at 4.5 K/hour. Finally, the samples were addi-
to have a less homogeneous gap with \( \sigma \) = 0.08 meV. Much of the variation comes from spectra near defects, where \( \Delta \) is reduced to a minimum of 5.7 meV. The homogeneity of the superconducting gap measured in LiFeAs by STS with sensitivity spectroscopic investigations. For comparison, the 122 iron arsenide compound BaFe\(_{1.8}\)Co\(_{0.2}\)As\(_2\) was found to have a less homogeneous gap with \( \sigma_\Delta/\Delta \approx 12\% \) [21]. An extreme example is the much-studied cuprate, BSCCO [22], where local inhomogeneities in doping result in strong variation in the gap magnitude. Hence, free from surface reconstruction or disorder induced by local dopants, LiFeAs presents an ideal system for surface sensitive spectroscopic investigations.

Taking a closer look at the STS in the vicinity of the superconducting gap in Fig. 3(a), two nodeless gaps are clearly resolved at 2 K. The two-gap superconducting excitation spectrum can be fitted within the framework of BCS, where the normalized quasiparticle density of
states $\tilde{N}(E)$ of a superconductor is defined as

$$\tilde{N}(E) = \sum_k \frac{N_s(E(\vec{k}))}{N_n \sqrt{(E(\vec{k}))^2 - (\Delta(\vec{k}))^2}}$$

(1)

with the superconducting DOS $N_s$ and normal states DOS $N_n$, being a function of the Cooper pair energy $E(\vec{k})$ and the single particle energy $\sqrt{E(\vec{k})^2 - (\Delta(\vec{k}))^2}$, respectively. If measured by the tunneling method, this can be described by Dynes’ formula [25],

$$\tilde{N}(E) = \sum_k \int Re \left[ \sum_{i=1}^{2} w_i \times \frac{\partial f(E - \epsilon_0 \vec{k})}{\partial E} \times \frac{\partial f(E - i\Gamma \vec{k})}{\partial E} \right] dE$$

(2)

where $f(E - \epsilon_0 \vec{k})$ is the Fermi-Dirac distribution function and $w_i$ is the weight of the contribution from the $i^{th}$ gap with the constraint of $w_1 + w_2 = 1$ [25]. The effective damping term $\Gamma(E) = \alpha E$ is used to properly represent zero DOS at $E_F$ [26]. We fit the 2 K STS over a bias range from -6.8 mV to 6.8 mV under the assumption that the normal density of states is linear over the small energy range examined: $N_n(E) = a + b \times E$.

Two different $\Delta(\vec{k})$ superconducting gap models were considered. One consists of two isotropic gaps, yielding $\Delta_1 = 5.33 \pm 0.10$ meV, $\Delta_2 = 2.50 \pm 0.15$ meV, $w_1=0.89$ and energy dependent $\Gamma = 0.13 \times E$. The other consists of two anisotropic gaps with four fold symmetry as observed by ARPES [13], yielding $\Delta_1 = 5.33 \times (1 + 0.09 \times \cos(4\theta)) \pm 0.1$ meV ($\Delta_{\text{max}} = 5.8$ meV), $\Delta_2 = 2.50 \times (1 + 0.20 \times \cos(4\theta)) \pm 0.20$ meV, $w_1=0.87$ and $\Gamma = 0.10 \times E$. Both gap models fit the 2 K STS very well within the fitting range (see for example the two-isotropic-gap model fit in Fig. 3(b)) and give gaps that are consistent with recently reported values obtained from STS [15, 16], giving reduced gaps of $\frac{\Delta_2}{k_B T_c} = 7.3$ and $\frac{2\Delta_2}{k_B T_c} = 3.4$. However, both of the fits clearly fail to represent the measured spectra outside the fitting range due to additional above gap features, which will be discussed further below.

The gap magnitudes obtained from fitting agree well with the largest and the smallest of the four gaps determined by ARPES [13]. Tunneling into the two electron pockets, containing the other two gaps, is expected to be strongly suppressed because of the larger in-plane momentum $|\vec{k}_i|$ [17, 27]. The small anisotropy factors obtained from the fit to two anisotropic gaps also agree well with ARPES results [13], reinforcing the consistency of the two surface sensitive measurements in LiFeAs. However, unlike the gap shapes previously reported by STS [13], the gaps shown in Fig. 3(a) and (b) are fully open and symmetric even at elevated temperatures.

Fig. 3(b) shows the temperature dependence of the STS spectra from 2 K to 20 K in the same defect-free region. Each spectrum is the average of 16 spectra acquired from a $4 \times 4$ nm$^2$ area. The superconducting gaps are visible up to 16.5 K and disappear at 17 K, manifesting the same $T_c$ seen in susceptibility. Based on the simpler isotropic gap assumption, which adequately represents the gap size given the small anisotropy factors found, the temperature dependence of the gap amplitudes was extracted, and is plotted with the Meissner transition measured by SQUID in Fig. 3(c). The temperature dependence of $\Delta_1$ follows BCS theory and the gap closes at the bulk $T_c$ value.

These results and the apparent absence of a surface state or electronic reconstruction [11, 12] suggest that the surface behavior echoes the bulk.

To more carefully examine the structure surrounding the superconducting gap, the STS below $T_c$ are normalized by the normal state conductance, $dI/dV(V)|_{17K}$ according to Eq. 1 shown in Fig. 3(a), and the second derivative was calculated numerically, shown in Fig 3(b). Here, features higher in energy than the coherence peaks are clearly visible, diminishing as the temperature approaches $T_c$. These features consist of a relatively well-defined dip below the normal state conductance, followed by a broad hump. These can be characterized by three different energies: $E_D \approx 10$ meV, $E_I \approx 12$ meV, and

FIG. 3. (a) Two isotropic gaps fit (blue line) on top of measured $dI/dV$ spectra (black line, 2 K). The dashed lines indicate the fitting bias range from -6.8 mV to 6.8 mV. (b) Temperature dependence of the superconducting gap measured by STS between 2 and 17 K. (c) The large gap determined by isotropic s-wave fits (red error bars) generally follows the temperature dependence predicted by the BCS weak coupling limit (dashed black line). The development of the smaller gap (blue error bars) is obscured by thermal broadening at elevated temperatures. The bulk $T_c$ of 17 K probed by SQUID magnetometry with a 1 G magnetic field (gray dots and right y-axis) agrees with the surface critical temperature, demonstrating agreement between surface and bulk properties.
The dip in the normalized $dI/dV$ second derivative of $I(V)$ at $2\, \text{K}$ reveals the position of the main features. The dip in the normalized $dI/dV$ is at $E_D \approx \pm 10\, \text{mV}$ and the inflection point/kink in $dI/dV$ is at $E_I \approx \pm 12\, \text{mV}$ (dashed line).

$E_H \sim 15\text{–}20\,\text{meV}$, the energy of the dip, inflection point between dip and hump, and the hump respectively. While the apparent bias asymmetry in the coherence peaks and dip-hump features are reminiscent of the cuprates, this may also arise from the normalization to the $17\,\text{K}$ spectrum which exhibits a hump at around $-5\,\text{mV}$ and a steep rise at positive bias, both of which are thermally broadened compared to the low temperature spectra.

The features observed in LiFeAs, characterized by a dip at $\sim 2\Delta$ from $E_F$ followed by a broader hump, bear striking resemblance to those observed in the cuprates. In past studies on superconducting cuprate materials, these features have been attributed to several different origins due to the large variety of competing effects at similar energy scales. These include inelastic tunneling effects, band structure effects, or non-pairing boson interactions. Other explanations are based on the pseudogap observed in the cuprates, but these are likely absent in the iron arsenides. In our data, the reduction of the tunneling conductance below the normal state indicates that inelastic tunneling effects are not responsible for these features, and band structure effects are unlikely in our spectra since the features disappear above $T_c$.

Thus, we turn our attention to possible boson interactions. In the well-established framework of phonon-based pairing in an $s$-wave superconductor, the energy dependence of the gap leads to an initial peak or shoulder outside the quasiparticle coherence peaks due to increased pairing strength, followed by a dip as the interaction switches from attractive to repulsive at the mode energy. Our spectra do not show this initial peak or shoulder. Regardless, features caused by coupling to a bosonic mode are expected to appear at the mode energy shifted by the gap $(\Omega + \Delta)$. Given the differences between our spectra and the classic phonon coupling case, combined with the lack of strong features in the phonon spectrum of LiFeAs below $\sim 14\,\text{meV}$, it seems unlikely that the features we observe arise from phonon mediated pairing. Spin fluctuation mediated superconductivity has been suggested in the pnictides, a theory also supported by STS data of SmFeAsO$_1-x$F$_x$. Indeed, recent reports from neutron scattering have indicated a broad magnetic excitation peaked around $5\text{–}8\,\text{meV}$, corresponding well with the energy of the dip shifted by the large gap, $E_D - \Delta_1 \approx 5\,\text{mEV}$.

The cuprates and the arsenides thus share a couple of features that suggest a common origin for the dip-hump. Both have a mode developing in the spin fluctuation spectrum when the superconducting gap appears below $T_c$. Both also have considerable damping of this mode due to non-zero density of states; in the cuprates this is due to nodes in the $d$-wave gap and in the arsenides this can arise from anisotropy as well as a finite density of states once above the energy of the small gaps associated with the multiband nature of the $s_\pm$ state. This may reasonably result in similar spectral shapes, however unambiguous assignment of the spectral features will require a proper microscopic theory including the pairing symmetry of LiFeAs. The energy scale of the features found here also draw a parallel to the cuprates. Zasadzinski et al. showed a clear proportionality of the boson mode energy $\Omega$ with $T_c$, that also agreed in magnitude with the magnetic resonance from inelastic neutron scattering for a wide range of $T_c$ from overdoped to underdoped BSCCO. They found that $\Omega/\Delta \approx 1$ for optimally doped samples and generally that $\Omega \approx 5k_B T_c$, confirmed for a wide range of cuprate superconductors.

The feature observed here for LiFeAs similarly sits at $\Omega/\Delta \approx 1$ and lies close to the $5k_B T_c = 7\,\text{meV}$, indicating a similar underlying mechanism.

The characteristics of LiFeAs presented here demonstrate that this material provides a comparatively simple system in which to study high-$T_c$ superconductivity. In stark contrast to the best cuprate materials, the superconducting gap remains remarkably homogeneous over large areas in LiFeAs. Additionally, the presentation of a non-polar cleaved surface, that does not reconstruct and accurately represents the bulk properties, makes it ideal for surface sensitive studies. Although this material shows multiple superconducting gaps, they are without nodes, and exhibit BCS-like temperature dependence. Yet, this material shows all the signs of strong coupling with a relatively large reduced gap of 7.3, and strong above gap features corresponding closely in energy with a magnetic resonance recently reported. The sum of these features offers a clearer view into the quasiparticle phenomenology and should serve as a testbed for new
understanding of superconductivity.

The authors would like to thank George Sawatzky, Giorgio Levy, Peter Hirschfeld and Steve Johnston for several helpful conversations.
