Background: The interaction between human prostate cancer (PCa) cells and bone marrow (BM) endothelium follows a rolling-and-adhesion cascade mediated by E-selectin ligand (ESL): E-selectin. This adhesion is enabled by elevated expression of α1,3-fucosyltransferases (FTs), enzymes responsible for ESL-mediated bone metastasis in humans. In contrast, the incidence of bone metastasis in mice is rare.

Methods: FT 3, 6 and 7 were overexpressed in mouse PCa cells. The rolling cell number, cell-rolling velocity and transendothelial migration were characterised in vitro. Fucosyltransferases-transduced mouse PCa cells expressing luciferase were inoculated into mice via left ventricle to compare the capability of bone metastasis. Mass spectrometry and immunoprecipitation were utilised for identification of ESLs.

Results: Overexpression of FT3, FT6 or FT7 restored ESLs and enabled mouse PCa cells to roll and adhere in E-selectin-functionalised microtubes, similar to trafficking of circulating PCa cells in BM vessels. Following intracardiac inoculation, FT6-transduced cells induced robust bone metastasis in mice. Inhibition of FT6 by a fucose mimetic significantly reduced bone metastasis. Importantly, comparison of FT3, FT6 and FT7 gene expression in existing clinical samples showed significant upregulation of FT6 in PCa-distant metastases.

Conclusion: FT6 is a key mediator of PCa cells trafficking to the BM. It may serve as a viable drug target in preclinical tests of therapeutics for reduction of PCa bone metastasis.

Prostate cancer (PCa) is the leading cause of cancer death among American men, second only to lung cancer in 2012. When detected at an early stage, the 5-year survival rate is close to 100%. In contrast, if diagnosed at a late stage with advanced metastatic disease, the 5-year survival decreases to 33% (Siegel et al., 2012). The most common metastatic sites of PCa are lymph nodes, bones, lung and liver (Wilt and Ahmed, 2013). Among these sites, bone is the most challenging organ for therapeutic intervention as bone metastasis can cause severe skeleton-related diseases such as bone pain, hypercalcemia, fractures and nerve compression syndromes (Saad et al., 2006; Sturge et al., 2011).

Metastasis to bone is a multistep cascade. Prostate cancer cells detached from the primary site must first invade a blood vessel, a process called intravasation. Through hematogenous dissemination, a sub-population of cells attach to bone marrow (BM) endothelial cells. This process is mediated by multiple receptor-ligand interactions under shear stress, referred to as a rolling-and-adhesion cascade (Li and King, 2012). This cascade further facilitates PCa cells to breach the bone endothelial layer (transendothelial migration; TEM) to establish micrometastases in the bone microenvironment (Barthel et al., 2013).

Bone marrow endothelial cells constitutively express E-selectin, which enables homing of hematopoietic stem cells expressing E-selectin ligands (ESLs) to the BM (Sackstein, 2012; Winkler et al., 2012). Recent studies have indicated that human PCa cells also express similar ESLs to interact and traverse the vasculature of the BM (Dimitroff et al., 2004, 2005; Barthel et al., 2013). E-selectin ligands comprise the tetrasaccharide sialyl Lewis X (sLe³) attached...
to the extracellular domain of glycoproteins or glycolipids. The synthesis of sLeX on such glycoproteins is catalysed in the Golgi compartment by members of the glycosyltransferase gene family. The final step involves the transfer of fucose to N-acetylgalactosamine at the terminal α-2, 3 sialo-lactosamine unit by α-2, 3-fucosyltransferases (FT) 3, 4, 5, 6 and/or 7 depending on the cell type (de Vries et al, 2001). Gene expression profiling and immunohistology in several human PCa cell lines have shown that the bone metastasis potential correlates well with the expression level of FTs (Barthel et al, 2008; Yin et al, 2010). To the contrary, the rare evidence of bone metastasis in mice genetically prone to PCa raises the question of whether mouse PCa cells express ESLs (Gingrich et al, 1996). Moreover, if they are absent in mouse PCa cells, can one develop a new mouse model with robust bone metastasis by increasing expression of functional ESLs?

**MATERIALS AND METHODS**

### Cell lines and mice.

The transgenic adenocarcinoma of the mouse prostate (TRAMP) cell lines TRAMP-C1 and TRAMP-C2 were obtained from American Type Culture Collection (ATCC; Rockville, MD, USA) and cultured in Dulbecco’s modified Eagle’s medium (Invitrogen, Grand Island, NY, USA) with 4 mM l-glutamine adjusted to contain 1.5 g l⁻¹ sodium bicarbonate and 4.5 g l⁻¹ glucose supplemented with 0.005 mg ml⁻¹ bovine insulin and 10 ng dehydroisoandrosterone, 90%; fetal bovine serum (BD Biosciences, San Jose, CA, USA), 5%; Nu-Serum IV (BD Biosciences), 5%. RM1 cells are a murine- androgen-insensitive PCa cell line, which were kindly provided by T Thompson (MD Anderson Cancer Center, Houston, TX, USA) for this study. RM1 cells were cultured in Dulbecco’s modified Eagle’s medium supplemented with 10% FBS. Human umbilical vein endothelial cells (HUVEC) were obtained from ATCC and cultured in vascular cell basal medium (ATCC) using the endothelial cell growth kit-BBE (ATCC PCS-100-040). Human umbilical vein endothelial cells were used to passage number 6. Six- to 8-week-old male C57BL/6 mice were purchased from Jackson Laboratory (Bar Harbor, ME, USA). Mice were housed in a SPF barrier animal facility at the Cornell University.

### Antibodies.

The following recombinant proteins or antibodies were employed to characterise ESLs in this study: recombinant mouse E-selectin/CD62E Fc chimera (R&D Systems, Minneapolis, MN, USA), PE goat anti-human IgG (Santa Cruz Biotech, Santa Cruz, CA, USA), FITC HECA-452 (BD Biosciences), PE anti-mouse PSGL-1 (BD Biosciences) and FITC anti-mouse CD44 (BD Biosciences). The following antibodies from BD Biosciences were used as isotype controls: FITC Rat IgG2b, FITC Rat IgM and PE Rat IgG1.

### Flow cytometry.

Cells were detached with enzyme-free Gibco Cell Disassociation Buffer (Invitrogen) and suspended at a concentration of 5 × 10⁵ cells in 100 µl cold PBS/1% bovine serum albumin (BSA). Primary antibodies or corresponding isotype control antibodies were incubated with cells for 30 min on ice. Following two washes with 1 ml PBS/1% BSA, fluorescence measurements were collected on an Accuri C6 flow cytometer (BD Biosciences). Data were analysed using the Flow Express software (De Novo Software, Los Angeles, CA, USA). Cells were gated based on forward and side scatter. For detection of ESLs, recombinant mouse E-selectin/CD62E Fc chimera was used at a concentration of 10 µg ml⁻¹. Cells were suspended at a concentration of 5 × 10⁵ cells in 100 µl cold binding buffer PBS/1% BSA/2 mM Ca²⁺ or control buffer PBS/1% BSA/1 mM EDTA. Incubation was performed for 30 min on ice. Cells were washed with binding buffer or control buffer twice and stained with secondary PE anti-human IgG for 30 min on ice.

### Western blotting and immunoprecipitation.

For western blotting, whole-cell lysates were prepared and separated by 8% SDS–PAGE as previously described (Bu et al, 2013). Membranes were incubated with primary antibodies HECA-452 (BD Biosciences), anti-β-actin (Santa Cruz Biotech) and recombinant mouse E-selectin-Fc (R&D Systems). All primary antibodies were diluted 1:1000. Mouse E-selectin-Fc was diluted to 1 µg ml⁻¹ in the presence of 2.5 mM CaCl₂. Immunoprecipitation was performed to identify E-selectin-reactive membrane protein as previously described (Matsumoto et al, 2005). Five hundred micrometres of precleared proteins were incubated with either 5 µg human IgG isotype or 5 µg mouse E-selectin-Fc. The prepared samples were separated and analysed by western blotting. Anti-CD44 (Biolegend, San Diego, CA, USA) was used at 1:1000 dilution in the blotting.

### Identification of E-selectin-Fc-reactive protein by mass spectrometry.

Lysates from empty vector-transduced samples were used as background control to exclude non-specific interaction with E-selectin-Fc.

### Retroviral production and transduction.

Retroviral vectors encoding human sLeX FT3, FT6, FT7 and retrovirus packaging helper plasmids pN8e-gagpol-deltaS and pN8e-VSV-G were utilised. Briefly, retroviral vectors and two helper plasmids were transduced into HEK293T cells by TransIT-LT1 Transfection Reagent (Mirus Biology, Madison, WI, USA). Virus supernatants were collected at 48 and 72 h after transfection. Virus supernatants were mixed with target cells in the presence of 8 µg ml⁻¹ polybrene (Santa Cruz Biotech) for 24 h. Afterwards, fresh media was added and cells were selected with 200 µg ml⁻¹ G418 for 2 weeks.

### Tumour cell TEM assay.

The QCM Tumor Cell Transendothelial Migration Assay kit (Millipore, Billerica, MA, USA) was used in this study. Briefly, 1 × 10⁶ endothelial cells in 250 µl endothelial cell culture medium were loaded into each insert. After cells grew to > 95% confluence, endothelial cell monolayers were activated with 20 ng ml⁻¹ of recombinant human TNF-α for 4 h. Tumour cells (1 × 10⁵) were suspended in 250 µl serum-free media and loaded into the insert. Tumour cells were allowed to migrate for 24 h at 37 °C. Cells that migrated to the bottom of the inserts were fixed with 100% methanol, stained with crystal violet and counted on a microscope.

### Preparation of E-selectin-functionalized microtube and rolling experiments.

Fifty centimetre-long microfenethane microtubes with 300 µm inner diameter (BrainTree Scientific, Braintree, MA, USA) were first washed with 1 × PBS and then coated with 10 µg ml⁻¹ of recombinant protein G (Calbiochem, Frankfurt, Germany) for 1 h at room temperature. Microtubes were incubated with 0.125 µg ml⁻¹ of recombinant mouse E-selectin/Fc chimera for 2 h. The surface was then blocked with 5% fat-free milk for 0.5 h to avoid non-specific interaction of cells with the tube surface. Tubes were washed with PBS a,b,c (PBS saturated with calcium chloride; Invitrogen) and dissociated monolayer cells at a concentration of 1 × 10⁶ cells per ml in PBS a,b,c were perfused through at 2 dyn cm⁻² using a syringe pump (IUTC Life Sciences, Woodland Hills, CA, USA). Functionalized microtubes were
secured to the stage of an Olympus IX81 motorised inverted microscope (Olympus America, Melville, NY, USA). A CCD camera (Hitachi, Tokyo, Japan) and DVD recorder (Sony Electronics, Tokyo, Japan) were used to record experiments. Videos were later analysed using in-house ImageJ (NIH, Bethesda, MA, USA) stack tools to quantify rolling velocities. The number of cells per frame of rolling video was manually counted.

Animal studies. All mice were handled according to the Guide for the Care and Use of Laboratory Animals in compliance with UK-based guidelines. All experimental procedures and protocols were approved by the Institutional Animal Care and Use Committee of Cornell University (Protocol number 2011-0051). Male C57BL/6 mice (age 6–8 weeks) were anaesthetised by 2.5% isoflurane on the day of injections. On day 0, anaesthetised animals were injected with 1 × 10^5 cells suspended in 100 μl sterile DPBS containing 300 μg/ml d-luciferin into the left ventricle of the heart by non-surgical means via a 29 G needle (BD Biosciences). After injection, mice were subject to bioluminescence imaging (BLI).

Bioluminescence imaging. Bioluminescence imaging was performed with a CCD camera mounted in a light-tight specimen box (Xenogen, Waltham, MA, USA). Imaging and quantification of signals were controlled by the acquisition and analysis software Living Image (Xenogen). Anaesthetised mice were placed in the IVIS Imaging System and imaged from ventral views ~10–15 min after intraperitoneal injection of d-luciferin at 150 mg kg⁻¹ body weight. For experiments on day 0, successful intracardiac injections were indicated by images showing systemic bioluminescence distributed throughout the animal. Only mice with evidence of a satisfactory injection continued in the experiments. Assessment of subsequent metastasis was monitored in vivo after 1 week.

Histology. Mouse hind legs were fixed in 4% formaldehyde in PBS overnight and then decalcified in 10% formic acid in 10% formalin/PBS overnight. Decalcified hind legs were embedded in paraffin after tissue processing (dehydration, clearance and impregnation). Serial sections (5 μm) from each tissue block were cut onto slides and every fifth section was stained with hematoxylin and eosin (H&E) as previously described (Granot et al, 2011). Hematoxylin and eosin-stained slides were imaged with an upright Olympus BX-50 microscope equipped with a Moticam 2300 colour camera (Cole-Parmer, Vernon Hills, IL, USA).

Statistical analysis. All statistical analyses were performed using GraphPad Prism 5.0a for Mac OS X (San Diego, CA, USA). One-way ANOVA followed by Tukey’s post test was used to compare statistical significance in the characterisation of rolling velocity, number of rolling cells, TEM and quantification of bioluminescence signals. When analysing gene expression of FTs in the NCBI database, significance was calculated by Student’s t-test.

RESULTS

Mouse PCa cells do not express ESLs. E-selectin is a transmembrane glycoprotein that binds ESLs through its extracellular domain in a Ca²⁺-dependent manner (Graves et al, 1994). Three representative mouse PCa cell lines (TRAMP-C1, TRAMP-C2 and RM1) were examined in this study. TRAMP-C1 and TRAMP-C2 were derived from the TRAMP mouse (Foster et al, 1997). This model was generated by overexpressing SV40, which suppresses p53 and Rb to mimic loss of function in tumour suppressor genes. In contrast, the RM1 cell line was developed from the mouse prostate reconstitution model (Thompson et al, 1989). This model overexpresses the oncogene Ras. To test their binding to mouse E-selectin, cells were incubated with dimerised E-selectin-human IgG Fc chimera and fluorescently labelled anti-human Fc. This measurement showed that all three cell lines express low level of ESLs (Figure 1A).

Mouse PCa cells express certain glycoprotein ESLs but not sLeα. The glycoproteins PSGL-1 and CD44 have been identified as ESLs in human PCa, colon cancer and breast cancer (Dimitroff et al, 2005; Burdick et al, 2006; Zen et al, 2008). It is not clear whether the lack of functional ESLs is because of the absence of similar glycoproteins or a lack of sLeα in mouse PCa cells (Figure 1B). Antibodies recognising mouse PSGL-1 and CD44 were applied to TRAMP-C1, TRAMP-C2 and RM1 cells. None of them were found to express PSGL-1; however, CD44 is present on the cell surface of all three cell lines (Figure 1C). These glycoproteins serve as scaffolds to present the tetrasaccharide sLeα, which can directly interact with E-selectin. Using an antibody that recognises sLeα (HECA-452), it was found that none of these mouse PCa cell lines express sLeα.
lines express sLe$^x$ (Figure 1C). Although previous work suggests that mouse ESLs are not recognised by the HECA-452 antibody because of differences in sialic-acid composition compared with human ESLs (Mitoma et al., 2009), it was found in the present study that the introduction of fucose by overexpression of $\alpha$-1,3 FTs restored the binding of HECA-452 to mouse cell lines. This validates the use of HECA-452 to identify sLe$^x$ in this work (Supplementary Figure 1). Thus, we may conclude that the lack of sLe$^x$ is likely responsible for the deficiency in E-selectin binding.

FT3, FT6 and FT7 induce functional ESL expression on mouse PCa cells. The final step of sLe$^x$ synthesis on glycoproteins involves the transfer of fucose to N-acetylglucosamine catalysed by $\alpha$-1,3-FT. The upregulation of $\alpha$-1,3 FT3, 6 and 7 in human metastatic PCa tissues motivates the examination of whether FT3, FT6 or FT7 could be involved directly in the expression of sLe$^x$ in mouse PCa cell lines (Barthel et al., 2008, 2009). cDNA-encoding human FT3, FT6 and FT7 were packaged into retroviral particles and transduced into the TRAMP-C1, TRAMP-C2 and RM1 cell lines to establish stable cell clones. Indeed, overexpression of FT3, FT6 or FT7 restored E-selectin-binding in mouse PCa cells compared with empty vector-transduced cell lines (Figure 2). Thus, overexpression of FTs completes the final step of sLe$^x$ synthesis and enables E-selectin binding in mouse PCa cells.

Characterisation of rolling behaviour of FT-transduced cells. We next examined E-selectin binding in a dynamic fluid flow system. A previously established flow-based microtube system was employed to mimic the bone microvascular environment.
Figure 4. α1,3 FTs induce differential TEM. (A) A cartoon depicting the TEM assay is shown. Nearly confluent HUVEC monolayers were stimulated with TNF-α for 4 h before PCa cells were seeded. (B–D) Number of cells that migrated through a monolayer of HUVEC after incubation for 24 h. Results are the mean ± s.e.m. of three experiments; *** P < 0.001.

Figure 5. FT6 induces the highest incidence of bone metastasis using TRAMP-C2 cells in C57BL/6 mice. (A) A cartoon illustrating the procedures including intracardiac injection and BLI is shown. (B) Quantification of bone metastases in femurs and tibias 1 week after inoculation of PCa cells. BLI signals collected on day 7 were normalised to whole-body BLI on day 0. FT6-induced statistically significant bone metastasis compared with empty vector, FT3 and FT7 groups. For each group, n = 6. The experiment was repeated twice; results are mean ± s.e.m. from two independent experiments; * P < 0.05, ** P < 0.01. (C) Representative BLI images taken 1 week after PCa inoculation. Heat bar is represented as counts. Bioluminescence imaging signals < 600 counts were considered noise and removed per manufacturer’s suggestion. (D) Representative images of H&E staining from BLI-positive areas. Bioluminescence imaging was found to come largely from femurs proximal to knee joints. Abbreviations: BM = bone marrow, T = tumour.
unable to modify CD44 to become a functional ESL. Human IgG immunoprecipitates were not reactive with anti-CD44. Immunoprecipitates from FTs-transduced TRAMP-C2 proteins were subjected to western blotting and immunostained with anti-CD44. Anti-CD44 antibodies were used as a loading control. HECA-452 mAb immunoprecipitates were not reactive with anti-CD44, indicating specific interaction between E-selectin and CD44. FT-transduced empty vector-transduced TRAMP-C2 served as a background control. Empty vector-transduced TRAMP-C2 was used as a background control. Anti-CD44 antibodies were used as a loading control. CD44 is a primary ESL following FT6 overexpression. FT6-transduced cells exhibited the slowest rolling velocity under physiological wall shear stress (WSS) through the microtube lumen, and their rolling behaviour was characterised by measuring the rolling velocity and total number of interacting cells. In all three cell lines, FT6-transduced cells developed the highest metastatic burden in the femur (Figures 5B and C). Further examination of BM invasion by H&E staining revealed that only FT6-transduced TRAMP-C2 cells established significant metastases in the femur proximal to the knee joint (Figure 5D). FT6 promotes the greatest potential for BM metastasis. We next investigated whether the differential rolling velocity and TEM are sufficient to lead to distinct BM metastases in immune-competent mice. Equal numbers of empty vector or FT-transduced TRAMP-C2 cells stably expressing firefly luciferase were injected into the left ventricle of C57BL/6 mice. The intracardiac route was selected to allow for systemic dissemination of CTCs before becoming entrapped in the microvessels of the lung (Campbell et al, 2012; Zou et al, 2013). One week after cell injection, bone metastases were quantified by measuring luminescence signal in the tibia and femur (Figure 5A). The bioluminescence signal from the tibias and femurs was normalised to whole-body luminescence signal taken on day 0. Consistent with the in vitro findings, FT6-transduced TRAMP-C2 cells developed the highest metastatic burden in the bone (Figures 5B and C). Further examination of BM invasion by H&E staining revealed that only FT6-transduced TRAMP-C2 cells established significant metastases in the femur proximal to the knee joint (Figure 5D).

Figure 6. CD44 is a primary ESL following FT6 overexpression. (A) Western blotting of membrane proteins from FT3-, FT6- and FT7-transduced TRAMP-C2 cells. Distinct patterns were identified after proteins were probed with E-selectin-Fc and anti-sLeα mAb HECA-452. Empty vector-transduced TRAMP-C2 served as a background control. Anti-β actin was used as a loading control. (B) E-selectin-Fc immunoprecipitates from FTs-transduced TRAMP-C2 proteins were subjected to western blotting and immunostained with anti-CD44. HECA-452 mAb immunoprecipitates were not reactive with anti-CD44, indicating specific interaction between E-selectin and CD44. CD44 is a primary ESL following FT6 overexpression. FT6-transduced cells exhibited the slowest rolling velocity under physiological wall shear stress (WSS) through the microtube lumen, and their rolling behaviour was characterised by measuring the rolling velocity and total number of interacting cells. In all three cell lines, FT6-transduced cells exhibited the slowest rolling velocity under physiological WSS of 2 dyn cm⁻² (Figure 3B). The rolling adhesion was Ca²⁺ dependent, as flushing with 1 mM EDTA abolished cell binding as expected for E-selectin adhesion (data not shown). In contrast, cells transfected with empty vector were unable to roll or interact with E-selectin-coated microtubes (Figure 3B). In addition, FT6-overexpressing cells displayed the highest number of rolling cells interacting with E-selectin-coated surfaces (Figure 3C, Supplementary Figure 2). The behaviour in this biomimetic in vitro system suggests that ESLs may support the recruitment of CTCs from circulation to the bone endothelium in vivo.

TEM of FT-transduced cells. After CTCs roll and form firm adhesions with the endothelial layer in BM microvessels, CTCs must breach this layer to establish micrometastases, a process referred to as TEM. To assess TEM capability, empty vector or FT-transduced TRAMP-C2 cells stably expressing firefly luciferase were injected into the left ventricle of C57BL/6 mice. The intracardiac route was selected to allow for systemic dissemination of CTCs before becoming entrapped in the microvessels of the lung (Campbell et al, 2012; Zou et al, 2013). One week after cell injection, bone metastases were quantified by measuring luminescence signal in the tibia and femur (Figure 5A). The bioluminescence signal from the tibias and femurs was normalised to whole-body luminescence signal taken on day 0. Consistent with the in vitro findings, FT6-transduced TRAMP-C2 cells developed the highest metastatic burden in the bone (Figures 5B and C). Further examination of BM invasion by H&E staining revealed that only FT6-transduced TRAMP-C2 cells established significant metastases in the femur proximal to the knee joint (Figure 5D).

FT6 expression correlates with clinical PCa progression. To identify candidate ESLs induced by the overexpression of FTs, the glycoproteins from total lysates of FT-transduced TRAMP-C2 cells were examined by western blotting. Both mouse E-selectin-Fc and HECA-452 identified protein bands of a similar size, indicating that the ESLs formed after overexpression of FTs are positive for sLeα- or sLeβ-like glycan (Figure 6A). Whereas FT3-transduced cells were not detectable by either E-selectin-Fc or HECA-452, FT6 and FT7 generated unique patterns of ESLs in the blots. It is possible that FT3-induced ESLs are primarily glycolipids or glycoproteins that cannot be readily detected because of the denaturation step of western blotting. Noting that the slowest rolling velocity and greatest TEM found in vitro as well as the highest incidence of bone metastasis in vivo was observed for FT6, the identity of unique glycoproteins was further validated through immunoprecipitation by beads conjugated to E-selectin-Fc (Figure 6B). Consistent with human studies, CD44 has been found to be a key protein that is involved in the adherence of metastatic prostate and breast cancer cells to BM endothelial cells (Draffin et al, 2004).

(For references, please see the original article.)
primary prostate tumours ($P = 0.05$) and metastatic tumours ($P = 0.001$) in comparison with normal prostate epithelium adjacent to primary PCa tumours (Figure 7B, Supplementary Table). No significant difference was found when examining FT3 and FT7 in the same tissues, except for an increase in FT3 expression in distant metastasis samples compared with normal prostate epithelium adjacent to tumours ($P = 0.04$; Figure 7A and C, Supplementary Table).

**α-1, 3-FT inhibitor reduces FT6-dependent bone metastasis.**

The in vivo experiments in this work along with gene expression profiles from clinical samples support the idea that FT6 may be one of the key mediators that drives bone metastasis. Thus, it is of therapeutic interest to explore whether the inhibition of FT6 can reduce bone metastasis in our mouse model. To this end, fluorinated fucose mimetic (2F-peracetyl-fucose) was utilised to inhibit the activity of FT6 (Figure 8A). Following 3 days of incubation with 20 μg ml$^{-1}$ 2F-peracetyl-fucose, FT6-transduced TRAMP-C2 showed reduced E-selectin binding (Figure 8B). This concentration did not compromise cell viability (data not shown), consistent with a prior study in which a three-fold higher concentration did not affect the viability of leukocytes.
Induction of bone metastasis in mouse PCAs by FT

(Barthel et al, 2012). To assay the efficacy of this fucose mimic in vivo, FT6-transduced TRAMP-C2 cells that received the same treatment or vehicle control (DMSO) were injected into C57BL/6 mice via the left ventricle. One week later, fucose mimic-treated cells produced significantly fewer and smaller bone metastases compared with DMSO treatment quantified by BLI (Figure 8C and D). As 2F-peracetyl-fucose is highly cell permeable and has not been shown to reduce cell viability in prior studies, we reason that it represents a potential therapeutic for the reduction of bone metastasis.

DISCUSSION

In this work, we aimed to dissect the molecular mechanism of why bone metastasis is a frequent occurrence in the human disease but rare in mouse. Our results indicated that the lack of functional ESLs in mouse cell lines may partly explain this discrepancy. As ESLs are composed of a scaffold protein or lipid decorated by the tetrasaccharide SL6, we further identified a lack of SL6 in mouse PCa cells. However, overexpression of human α1,3 FTs in mouse PCa cells restored E-selectin binding and led to the rolling of PCa cells in E-selectin-coated microtubes under physiological flow conditions. Interestingly, the different FTs (FT3, FT6 and FT7) showed differential rolling velocities and TEM capability in vitro. Among the three mouse PCa cell lines tested (TRAMP-C1, TRAMP-C2 and RM1), FT6-transduced cells showed the slowest rolling velocity and the highest degree of TEM. To correlate these in vitro findings with in vivo metastatic potential, we inoculated FT-transduced TRAMP-C2 cells labelled with firefly luciferase into the left ventricle of wild-type C57BL/6 mice. Within 1 week, the FT6-overexpressing cells promoted significant bone metastasis in the tibia and femur as detected by BLI. We further identified CD44 as a primary ESL in cells expressing FT6 but not FT3 or FT7. This correlates with previous studies in human cells where CD44 promotes the adherence of metastatic cancer cells and mesenchymal stem cells to BM endothelial cells (Draffin et al, 2004; Burdick et al, 2006; Sackstein et al, 2007; Zen et al, 2008; Sackstein, 2012).

Interestingly, previous work by the Dimitroff lab showed that FT7 rather than FT3 or FT6 promoted trafficking of human PC3 PCA cells to immunodeficient mouse BM (Barthel et al, 2009). This may reflect inherent species-dependent differences between mouse and human-derived PCA cells. It should be noted that the mouse genome does not include the FT3 or FT6 genes and only FT4 and FT7 have been found to be elevated in other human bone metastatic PCa cells. However, overexpression of human α1,3 FTs in mouse PCa cells restored E-selectin binding and led to the rolling of PCa cells in E-selectin-coated microtubes under physiological flow conditions. Interestingly, the different FTs (FT3, FT6 and FT7) showed differential rolling velocities and TEM capability in vitro. Among the three mouse PCa cell lines tested (TRAMP-C1, TRAMP-C2 and RM1), FT6-transduced cells showed the slowest rolling velocity and the highest degree of TEM. To correlate these in vitro findings with in vivo metastatic potential, we inoculated FT-transduced TRAMP-C2 cells labelled with firefly luciferase into the left ventricle of wild-type C57BL/6 mice. Within 1 week, the FT6-overexpressing cells promoted significant bone metastasis in the tibia and femur as detected by BLI. We further identified CD44 as a primary ESL in cells expressing FT6 but not FT3 or FT7. This correlates with previous studies in human cells where CD44 promotes the adherence of metastatic cancer cells and mesenchymal stem cells to BM endothelial cells (Draffin et al, 2004; Burdick et al, 2006; Sackstein et al, 2007; Zen et al, 2008; Sackstein, 2012).

Previously, the authors of this work studied the role of ESLs in breast cancer cell TEM and that E-selectin-blocking antibody can functionally abolish this migration in vitro (Zen et al, 2008). Although it is not clear whether FT has a role in the TEM of breast cancer cells, it was shown that ESLs prime TEM of human breast cancer cell TEM in vitro (Zen et al, 2008). This newly developed experimental metastasis model has several advantages over existing mouse models of bone metastasis: (1) It bypasses complicated surgical implantation of PCa cells in the bone. Moreover, the direct intraosseous implantation bypasses several crucial steps in the metastatic cascade: survival in the bloodstream, rolling and extravasation (McCabe et al, 2008); (2) Is less time consuming than iterative selection of the bone metastatic PCa cells (Power et al, 2009); (3) the use of wild-type mouse allows for the study of PCa development in an immunocompetent background, which considers the involvement of the immune system.
