Measuring Dark Matter at a Collider

Andreas Birkedal

Abstract. We investigate the need and prospects for measuring dark matter properties at particle collider experiments. We discuss the connections between the inferred properties of particle dark matter and the physics that is expected to be uncovered by the Large Hadron Collider (LHC) and the International Linear Collider (ILC) and motivate the necessity of measuring detailed dark matter properties at a collider. We then investigate a model-independent signature of dark matter at a collider and discuss its observability. We next examine the prospects for making precise measurements of dark matter properties using two example points in minimal supergravity (mSUGRA) parameter space. One of the primary difficulties encountered in such measurements is lack of constraint on the masses of unobservable heavy states. We discuss a new method for experimentally deriving estimates for such heavy masses and then conclude.

Keywords: Dark Matter, Collider Measurements

INTRODUCTION

The existence of non-baryonic, non-luminous matter appears now to be firmly established. The amount of such 'dark' matter has been measured at the 10% level. The current best limit is given in terms of $\Omega_\chi h^2$, the fractional energy density of the universe that is contained in dark matter, and $\Omega_\chi h^2$ is the reduced Hubble parameter:

$$0.094 \leq \Omega_\chi h^2 \leq 0.129 \quad \text{(at 2\sigma)} . \quad (1)$$

The nature of dark matter is one of the greatest unsolved mysteries of science. Usually, one hypothesizes an extra stable electrically neutral particle that can serve as dark matter. Most particle physics models that attempt to explain the weak scale and electroweak symmetry breaking contain such additional particles among their non-Standard Model particle spectra. Since one of these models might be discovered at the LHC or ILC, it is interesting to ask what, if anything, such colliders can tell us about dark matter. This talk focuses specifically on answers to this question.

CONNECTIONS BETWEEN DARK MATTER AND COLLIDERS

Precious little is known about dark matter, except for its gross density, given in Eqn. (1). If one assumes that dark matter comes from a thermal relic, this gross density is, in large part, determined by the dark matter annihilation cross section: $\sigma (\chi \chi \rightarrow SM SM)$. In fact, the present-day dark matter abundance is roughly inversely proportional to the thermally averaged annihilation cross section times velocity $\langle \sigma v \rangle$: $\Omega_\chi h^2 \propto 1/\langle \sigma v \rangle$. Figure 1 shows the constraint on the annihilation cross section as a function of dark matter mass that results from Eqn. (1). Remarkably, this constraint is effectively independent of dark matter mass, and points to cross sections expected from weak-scale interactions (around 0.8 pb for s-annihilators and 6 pb for p-annihilators). It points to the possibility that the solution to the dark matter puzzle is connected to the explanation for the weak scale, leading to the idea of Weakly Interacting Massive Particle (WIMP) dark matter. Such WIMPs exist not only in supersymmetric theories, but also in theories involving extra dimensions as well. The LHC and the ILC are specifically designed to probe the origin of the weak scale, so dark matter and future collider physics appear to be intimately connected.

Many experiments exist that hope to discover dark matter at many distances from earth. However, they, by themselves, are not able to solve the dark matter puzzle. Direct detection experiments hope to measure the mass of dark matter particles and their scattering cross section off atomic nuclei, $\sigma (\chi N \rightarrow \chi N)$. Since any measured rate of scattering depends on the number of degrees of freedom at the time of freeze-out as the dark matter mass is changed.

1. Plenary talk given at PASCOS05, Gyeongju, Republic of Korea, June 2005.

2. Usually the cross section times velocity can be conveniently expanded in powers of relative dark matter particle velocity: $\sigma v = \sum J \sigma_0 J (v^2 J)$. Commonly only the lowest order non-negligible power of $v$ dominates. For $J = 0$, such dark matter particles are called s-annihilators, and for $J = 1$, they are called p-annihilators; powers of $J$ larger than 1 are rarely needed.

3. This effect is due to the changing number of degrees of freedom at the weak scale, so dark matter and future collider physics appear to be intimately connected.
number of dark matter particles present, astrophysical uncertainties in halo models affect the accuracy of measurements. Furthermore, to claim that the dark matter puzzle has been solved, we must determine that a given particle (or set of particles) can provide the correct \( \langle \sigma v \rangle \) shown in Fig. 1. It is generically not possible to relate \( \sigma(N \rightarrow \chi N) \) to the required \( \sigma(\chi \chi \rightarrow SM SM) \). Indirect detection experiments attempt to discover dark matter through its present-day annihilation in regions of high density such as the galactic center. Again, significant astrophysical uncertainties exist. Also, these experiments hope to measure either a single annihilation final state, such as \( \sigma(\chi \chi \rightarrow \nu \nu) \), or a subset of final states, such as those with charged particles in the final state. While these final states do contribute to \( \sigma(\chi \chi \rightarrow SM SM) \), again, there is not a model-independent relation between the two. As a result, it is necessary to make detailed measurements of the particles and couplings involved in dark matter annihilation. These detailed measurements can only be done at particle collider experiments, such as the LHC and ILC.

**MODEL-INDEPENDENT COLLIDER SEARCH FOR DARK MATTER**

Since the WIMP hypothesis and the known abundance of dark matter give specific values for the dark matter annihilation cross section, one might hope this cross section can be turned into a rate for a measurable process at a particle collider. Such a model-independent collider signature does indeed exist \(^4\) and has implications for indirect detection experiments \(^5\).

To arrive at the model-independent signature, we start with cosmological data, namely the allowed values for \( \sigma_{\text{ann}} \) from Fig. 1. We introduce the parameter \( \kappa_c \):

\[
\kappa_c \equiv \frac{\sigma(\chi \chi \rightarrow e^+ e^-)}{\sigma(\chi \chi \rightarrow SM SM)}
\]

This equation relates the dark matter annihilation cross section to the cross section involving \( e^+ e^- \) in the final state. Then we use crossing symmetries to relate \( \sigma(\chi \chi \rightarrow e^+ e^-) \) to \( \sigma(e^+ e^- \rightarrow \chi \chi) \). Finally, we use collinear factorization to relate \( \sigma(e^+ e^- \rightarrow \chi \chi) \) to the process \( e^+ e^- \rightarrow \chi \chi \gamma \). We thus have gone from cosmological data, in the form of \( \sigma_{\text{ann}} \), to a prediction for the rate \( e^+ e^- \rightarrow \chi \chi \gamma \):

\[
\frac{d\sigma}{dx d\cos \theta} (e^+ e^- \rightarrow 2\chi + \gamma) \approx \frac{\alpha \kappa_c \sigma_{\text{ann}}}{16\pi} \left[ 1 + \left( \frac{1}{1 - x} \right)^2 \sin^2 \theta \right] \left( \frac{4M^2_\chi}{(1 - x)^2} \right)^{1/2 + j_0}.
\]

Here \( x = 2E_\gamma/\sqrt{s}, \theta \) is the angle between the photon and the incoming electron, \( S_\chi \) is the spin of the WIMP, and \( J_0 \) is the dominant value of \( J \) in the velocity expansion for \( \sigma v \), defined earlier.

The accuracy of our method is illustrated in Figure 2. The left panel in Figure 2 shows how the formula in Eqn. 3 (green line, labelled as 'Eq. (9)') compares with the exact calculation in a supersymmetric theory (red line, labelled 'MSSM') with a WIMP mass of 225 GeV. It is clear that the agreement is quite good, especially for the harder photons, which are most useful in our approach. The right panel shows the expected reach in \( \kappa_c \) for a 500 GeV linear \( e^+ e^- \) collider as a function of the WIMP mass. We have included background from \( e^+ e^- \rightarrow \nu \nu \gamma \). We show the 3σ contour (black solid line) including statistical errors and also indicate the values one might expect from supersymmetric models (the region below the red dashed line labelled 'SUSY'). It is clear that this signal, while challenging, could provide direct evidence of WIMP production at colliders.

**TESTING SUPERSYMMETRIC COSMOLOGY AT THE ILC**

The above model-independent rate is rarely the dominant collider signature of new physics within a given

---

\(^4\) Due to space restrictions, here we are skipping many intermediate steps. For further detail, we refer the reader to the original paper, Ref. 3.
model. It therefore makes sense to look at more model-dependent processes; we choose the minimal supersymmetric extension of the Standard Model (MSSM). The WIMP is taken to be the lightest supersymmetric particle (LSP), usually the lightest neutralino, $\tilde{\chi}_1^0$. If the LSP is the dark matter particle, the generic collider signatures of supersymmetry all involve missing energy due to the two stable $\tilde{\chi}_1^0$’s escaping the detector. In order to prove that the missing energy particle is indeed a viable WIMP dark matter candidate, one needs to calculate its expected present relic abundance. One thus needs to measure all parameters which enter the calculation of $\langle \sigma v \rangle$. In the most general MSSM there are more than 100 input parameters at the weak scale, but fortunately, a lot of them are either tightly constrained or not very relevant for the dark matter calculation. Nevertheless, there are still several relevant parameters left; they must be determined from collider data. Of course, the relevance of any one parameter depends sensitively on the parameter space point. We now look at two points: first, a point from the ‘bulk region,’ and then a point from the ‘focus point region,’ both from mSUGRA, a convenient subset of the larger MSSM.

Our first point, point B’ from the bulk region, is defined by the following input parameters:

$m_0 = 57$ GeV, $m_{1/2} = 250$ GeV, $A_0 = 0$, $\tan \beta = 10$ and sign$(\mu) = +1$.

Fig. 3 shows that the particle spectrum at this point is quite light. The two lightest neutralinos, the lightest chargino and all of the sleptons have masses below 200 GeV. All of the squarks are lighter than 600 GeV. The heaviest particle, the gluino, only weighs 611 GeV. Therefore, one would expect colliders to have significant discovery and measurement capabilities.

We first estimate the sensitivity of $\Omega h^2$ to the various SUSY parameters, and then we determine the precision with which they can be measured at colliders. In Fig. 4 we show the sensitivity of the dark matter relic density to 6 relevant MSSM parameters. In each panel, the green region denotes the 2σ WMAP limits on $\Omega h^2$ and the red line shows the variation of the relic density as a function of the corresponding parameter. The vertical (blue-shaded) bands denote parameter regions currently ruled out by experiment. The blue dot in each panel denotes the

---

5 Here we have used Isajet 7.69 and DarkSUSY except for calculations where coannihilations are important, in which case we have used microOMEGAS.
nominal value for the corresponding parameter at point B’.

The importance of the different SUSY parameters for the determination of the neutralino relic density can be judged from the slope of the lines in Fig. 4. If \( \Omega \chi_\nu \) is sensitive to a given parameter, the corresponding line will be flat. Conversely, if the relic density is particularly sensitive to some SUSY parameter, the slope of the corresponding variation curve will be very steep. Interestingly enough, Fig. 4 also shows that even for one given parameter, there are regions where this parameter can be important (for example \( M_{\tilde{b}_R} \) at low masses, where coannihilation processes with bottom squarks become important), as well as regions where this parameter has very little impact on the relic density (e.g. \( M_{\tilde{b}_R} \) at its nominal value). Therefore, in estimating the uncertainty on \( \Omega \chi_\nu \), it is now straightforward to estimate the uncertainty in \( \Omega \chi_\nu \) and Higgs pole formation will be available. Finally, in terms of Higgs bosons, we expect a detection only of the lightest (Standard Model-like) Higgs boson and the absence of a heavy Higgs boson signal will simply place the bound \( M_A \geq 200 \text{ GeV} \).

Our assumptions about the corresponding precision at a 500 GeV ILC were the following. Since superpartners need to be pair-produced, we take all particles lighter than 250 GeV to be observable, and their masses can be measured to within 2%. This includes the same chargino-neutralino states as in the case of LHC, plus all sleptons.

From Fig. 4 we see that with the assumptions above, the LHC (scheduled to turn on in 2007) is not competitive with the current state of the art determination of the relic density from cosmology. Nevertheless, it will bound the relic density from above and below, and may provide the first hint on whether the dark matter candidate being discovered at colliders is indeed the dark matter of cosmology. The ILC will fare much better, and will achieve a precision rivaling that of the cosmological determinations.

Turning to point LCC2, we show in Fig. 6 the spectrum of particle masses. We also show the analogous variation of the relic density as a function of 5 relevant parameters. Here the squark and slepton masses are heavy and have little impact on the actual \( \Omega \chi_\nu \). For this point, the lightest neutralino is mostly Bino, but with a non-negligible higgsino component.

Fig. 6(a) shows the dependence of \( \Omega \chi_\nu \) on the Bino mass parameter \( M_1 \). As expected, lowering \( M_1 \) increases the Bino component of the LSP, thus suppressing \( \sigma_{\text{ann}} \) and increasing \( \Omega \chi_\nu \). Fig. 6(b) exhibits complementary behavior: the \( M_2 \) parameter controls the wino fraction of the LSP, and small values of \( M_2 \) lead to wino-like dark matter, which has a large annihilation rate and therefore smaller relic abundance. Again, see Ref. [9] for further details.

These results will be combined with the outcome of a comprehensive simulation study, including detailed detector simulation, on the expected experimental precision at a 500 GeV ILC for point LCC2. The final product will be the analogue of Fig. 5 for point LCC2. For further details on the current status of this analysis, see [9].

---

6 Neutralino dark matter with significant wino content has been studied in the contexts of scenarios with non-universal gaugino masses [10], string-derived supergravity [11] and anomaly-mediated supersymmetry breaking [12].
FIGURE 4. Effect on relic density of varying relevant SUSY mass parameters for point B’. The horizontal (green-shaded) region denotes the 2σ WMAP limits on the dark matter relic density. The red line shows the variation of the relic density as a function of the corresponding SUSY parameter. The vertical (blue-shaded) bands denote parameter regions currently ruled out by experiment. The blue dot in each plot denotes the nominal value for the corresponding parameter at point B’. Taken from Ref. [9].

FIGURE 5. Accuracy of WMAP (horizontal green shaded region), LHC (outer red rectangle) and ILC (inner blue rectangle) in determining $M_{\chi}$, the mass of the lightest neutralino, and its relic density $\Omega_{\chi} h^2$. The yellow dot denotes the actual values of $M_{\chi}$ and $\Omega_{\chi} h^2$ for point B’. Taken from Ref. [9] and Ref. [7].

MEASURING SLEPTONS AT THE LHC

As discussed in the previous section, slepton masses are among the key parameters in determining whether $\tilde{\chi}^0_1$ is a good dark matter candidate [16]. Without a collider measurement of the slepton mass, there may be a significant uncertainty in the relic abundance calculation. This uncertainty results because the slepton mass should then be allowed to vary within the whole experimentally allowed range.

The importance of slepton discovery is two-fold. First, supersymmetry predicts a superpartner for every standard model particle. Therefore, the discovery of the superpartners of the leptons is an important step in verifying supersymmetry. Second, knowledge of slepton masses is always important for an accurate determination of the relic abundance of $\tilde{\chi}^0_1$.

Here we show that the LHC will indeed have sensitivity to mSUGRA slepton masses, even in the case of heavy sleptons [17]. We show that the difference between real and virtual sleptons can be clearly seen. We also show that in case of virtual sleptons, one can frequently limit the allowed range of their masses, which is equivalent to a rough indirect slepton mass measurement.

Slepton studies at the LHC are challenging. Direct production of sleptons suffers from large backgrounds, mostly due to $W^+W^-$ and $t\bar{t}$ production [18]; the methods for slepton mass determination used at the linear collider are not applicable here. Fortunately, sleptons are produced in sizable quantities at the LHC through cascade decays. These events can be easily triggered on and separated from the standard model backgrounds. A common hierarchy in supersymmetric models is $|M_1| < |M_2| < |\mu|$. In that case, sleptons affect the decay $\tilde{\chi}^0_2 \rightarrow \ell^\pm \ell^\mp \tilde{\chi}^0_1$. The resulting dilepton distribution, in principle, contains information about the slepton mass $m_\ell$. This sit-
What is the observable in these events that is sensitive to the slepton mass? In this analysis we will consider the dilepton invariant mass distribution, $m_{\ell\ell}$. The endpoint of $m_{\ell\ell}$ contains information about the masses of the real particles involved in the decay [19]. But there is more information contained in the $m_{\ell\ell}$ distribution than just in the endpoint [17]. One would expect the shapes of the $Z$ and $\tilde{\ell}$ mediated distributions to be different. Furthermore, the shape of the total decay distribution (including both $Z$ and $\tilde{\ell}$ contributions) should change as a function of the slepton mass. Indeed this is the case, as illustrated in Figure 4. Here we show the dilepton invariant mass distribution resulting from the interference of the $Z$ and $\tilde{\ell}_R$-mediated diagrams. The kinematic endpoint is kept fixed; this illustrates that endpoint analyses are largely insensitive to the slepton mass. In all four cases, the slepton is virtual, but we see a clear difference in the shape of the distribution. In the case of two body decay through a real slepton, the $m_{\ell\ell}$ distribution will be triangular, as required by phase space. It is also clear that the $m_{\ell\ell}$ distribution changes significantly as a function of slepton mass.

How does one use this fact to statistically differentiate between distributions coming from sleptons of different mass? The Kolmogorov-Smirnov (K-S) test provides a statistical procedure for differentiating between such distributions [20]. The K-S test calculates the maximum cumulative deviation between two unit-normalized distributions. It then translates this number into a confidence level with which it can be excluded that the two distributions come from the same underlying distribution. So, the K-S test cannot tell that two distributions came from the same underlying distribution, but it can tell that two distributions did not come from the same underlying distribution. We use this test to explicitly investigate the ability of the LHC to determine slepton masses in mSUGRA.

FIGURE 6. Upper left panel: Mass spectrum of point LCC2 from the focus point region. Other panels: Same as Fig. 4 but for point LCC2. Taken from Ref. [9].

FIGURE 7. Comparison of $M_{\mu^+\mu^-}$ distributions for different selectron masses. We only consider the diagrams mediated by $Z$ and $\tilde{e}_R$. All parameters are held fixed except for the $\tilde{e}_R$ mass. The (green, blue, red, black) line is for a (300, 500, 1000 GeV, and $\infty$) mass selectron, respectively. The neutralino masses are kept constant, and their difference is 88 GeV. Taken from Ref. [17].
We now demonstrate a slepton mass measurement at the LHC in mSUGRA parameter space. We select 1000 events that contain the decay of $\tilde{\chi}_1^0 \rightarrow e^+ e^- \tilde{\chi}_1^0$. We imagine that the LHC experiments have observed the dilepton mass distribution and have measured a kinematic endpoint at 59 GeV. The points with this same kinematic endpoint are the solid lines (blue for $A_0 = 0$ and tan$\beta = 10$). The plot shows the effect on the mSUGRA parameter space of fixing the dilepton kinematic endpoint of the $\tilde{\chi}_1^0 \rightarrow e^+ e^- \tilde{\chi}_1^0$ decay to be $m_{\tilde{e}_L,\tilde{\chi}_1} = 59$ GeV. It also shows the ability of the K-S test to bound the mass of the lightest selectron for light virtual sleptons. Details are explained in the text and Ref. [17].

In Figure 8, we also display the power of the K-S test in identifying the mass range of the slepton. We have taken one point (denoted by the black star) as resulting from a possible experimental measurement involving 1000 signal events. Then we have compared this “experimental data” with template distributions (denoted by the red and yellow dots). The red dots indicate points that the K-S test can identify as not coming from the same distribution as our “experimental data” at the 95% confidence level. The yellow dots denote points that could not be excluded at the 95% confidence level. We can rule out at the 95% confidence level almost all of the example template points except for the ones with the same value of $\mu$, but with almost identical values of $M_0$. Thus, the mass of the slepton can be determined with some accuracy even though it is not produced as a real particle. Analysis of experimental points with other values of the slepton mass can be found in Refs. [17, 21].

**CONCLUSION**

In this talk, we have introduced techniques and concepts for measuring dark matter at colliders. We have motivated why this should be possible and also why it is absolutely necessary to validate any claim of a solution to the dark matter puzzle. We have discussed a challenging model-independent signature of dark matter. We have also investigated the prospects for making precise measurements of cosmologically relevant parameters in a model-dependent approach. Finally, we discussed a new technique with implications for dark matter determinations at a collider that allows slepton masses to be measured at the LHC, even for heavy virtual sleptons.
