Topological photonics

Ling Lu*, John D. Joannopoulos and Marin Soljačič

The application of topology, the mathematics of conserved properties under continuous deformations, is creating a range of new opportunities throughout photonics. This field was inspired by the discovery of topological insulators, in which interfacial electrons transport without dissipation, even in the presence of impurities. Similarly, the use of carefully designed wavevector-space topologies allows the creation of interfaces that support new states of light with useful and interesting properties. In particular, this suggests unidirectional waveguides that allow light to flow around large imperfections without back-reflection. This Review explains the underlying principles and highlights how topological effects can be realized in photonic crystals, coupled resonators, metamaterials and quasicrystals.

In this Review, we present the key concepts, experiments and proposals in the field of topological photonics. Starting with an introduction to the relevant topological concepts, we introduce the 2D quantum Hall phase through the stability of Dirac cones7,8, followed by its realizations in gyromagnetic photonic crystals7,9,10, coupled resonators7,10,11 and waveguides11,12,13,14. We then extend our discussion to three dimensions, wherein we describe the stability of line nodes and Weyl points and their associated surface states12. We conclude by considering the outlook for further theoretical and technological advances.

Topological ideas in photonics branch from exciting developments in solid-state materials, along with the discovery of new phases of matter called topological insulators1–2. Topological insulators, being insulating in the bulk, conduct electricity on their surface without dissipation or back-scattering, even in the presence of large impurities. The first example of this was the integer quantum Hall effect, discovered in 1980. In quantum Hall states, two-dimensional (2D) electrons in a uniform magnetic field form quantized cyclotron orbits of discrete energies called Landau levels. When the electron energy sits within the energy gap between the Landau levels, the measured edge conductance remains constant within an accuracy of around one part in a billion, regardless of sample size, composition and purity. In 1988, Haldane proposed a theoretical model for achieving the same phenomenon in a periodic system without Landau levels3 — the quantum anomalous Hall effect.

In 2005, Haldane and Raghu transferred the key feature of this electronic model to the realm of photonics4,5. They theoretically proposed the photonic analogue of the quantum (anomalous) Hall effect in photonic crystals6 (the periodic variation of optical materials that affects photons in the same manner as solids modulate electrons). Three years later, this idea was confirmed by Wang et al., who provided realistic material designs and experimental observations8. These studies spurred numerous subsequent theoretical6–13 and experimental investigations14–16.

In ordinary waveguides, back-reflection is a major source of unwanted feedback and loss that hinders large-scale optical integration. The works cited above demonstrate that unidirectional edge waveguides transmit electromagnetic waves without back-reflection even in the presence of arbitrarily large disorder. This is an ideal transport property that is unprecedented in photonics. Topological photonics promises to offer unique, robust designs and new device functionalities for photonic systems by providing immunity to performance degradation induced by fabrication imperfections or environmental changes.
of both ordinary (left) and gapless (right) waveguides. On the left, the ordinary waveguide dispersion is disconnected from the bulk bands and can be continuously moved out of the frequency gap into the bulk bands. On the right, however, the gapless waveguide dispersion connects the bulk frequency bands above and below the frequency gap. It cannot be moved out of the gap by changing the edge terminations. Similar comparisons between the edge band diagrams are shown in Fig. 2. The only way to alter these connectivities is through a topological phase transition; that is, closing and reopening the bulk frequency gap.

The unidirectionality of the protected waveguide modes can be seen from the slopes (group velocities) of the waveguide dispersions. An ordinary waveguide (Fig. 1d, left) supports bidirectional modes because it back-scatters at imperfections. In contrast, a topologically protected gapless waveguide (Fig. 1d, right) is unidirectional as it has only positive (or only negative) group velocities. In addition, there are no counter-propagating modes at the same frequencies as the one-way edge modes. This enables light to flow around imperfections with perfect transmission — the light can only go forwards. The operating bandwidth of such a one-way waveguide is as large as the size of the bulk frequency gap.

From Dirac cones to quantum Hall topological phase

One effective approach for finding non-trivial mirrors (frequency gaps with non-zero Chern numbers) is to identify the phase transition boundaries of the system in the topological phase diagram, where the bulk frequency spectrum is gapless. Correct tuning of the system parameters thus open gaps that belong to different topological phases. In 2D periodic systems, these phase boundaries are point-degeneracies in the bandstructure. The most fundamental 2D point degeneracy is a pair of Dirac cones with linear dispersion between two bands. In three dimensions, the degeneracies involve line nodes and Weyl points, which we will discuss later in this Review.

Dirac cones are protected, in the entire 2D Brillouin zone, by PT symmetry, which is the product of time-reversal symmetry (T, Box 2) and parity (P) inversion. Every Dirac cone has a quantized Berry phase (Box 1) of π looped around 2π. Protected Dirac cones generate and annihilate in pairs.\(^{15-21}\) The effective Hamiltonian close to a Dirac point in the x−y plane can be expressed by \(H(\mathbf{k}) = v\mathbf{k}\cdot\mathbf{\sigma} + \mathbf{v}_c\cdot\mathbf{\sigma}_z\), where \(v\) are the group velocities and \(\sigma_i\) are the Pauli matrices. Diagonization leads to the solution \(\omega(\mathbf{k}) = \pm\sqrt{(v_c^2 + k_x^2)}\). Although both \(P\) and \(T\) map the Hamiltonian from \(\mathbf{k}\) to \(-\mathbf{k}\), they differ by a complex conjugation: \((PT)H(\mathbf{k}) = (PT)^{-1} = H(\mathbf{k})^*\). PT symmetry requires the Hamiltonian to be real and thus absent of \(\sigma_z\), which is imaginary. A 2D Dirac point-degeneracy can be lifted by any perturbation that is proportional to \(\sigma_z\) in the Hamiltonian or, equivalently, by any perturbation that breaks PT. Therefore, breaking either \(P\) or \(T\) will open a bandgap between the two bands.

However, the bandgaps opened by breaking \(P^2\) and \(T\) individually are topologically inequivalent\(^{15,25}\), as the bulk bands in these two cases carry different Chern numbers. The Chern number is the integration of the Berry curvature (\(T(\mathbf{k})\) in Table B1) on a closed surface in wavevector space. \(T(\mathbf{k})\) is a pseudovector that is odd under \(T\) but even under \(P\). In the presence of both \(P\) and \(T\), \(T(\mathbf{k}) = 0\). When either \(P\) or \(T\) is broken, the Dirac cones open and each degeneracy-lifting contributes a Berry flux of magnitude \(\pi\) to each of the bulk bands. In the presence of \(T\) (\(P\) broken), \(T(\mathbf{k}) = -T(\mathbf{k})\). The Berry flux contributed by one pair of Dirac points at \(\mathbf{k}\) and \(-\mathbf{k}\) are of opposite signs. Integration over the whole 2D Brillouin zone always equals zero, and thus so do the Chern numbers. In contrast, in the presence of \(P\) (\(T\) broken), \(T(\mathbf{k}) = T(\mathbf{k})\). Here, the total Berry flux adds up to \(2\pi\) and the Chern number equals one. More pairs of Dirac cones can lead to higher Chern numbers\(^{13}\). This \(T\)-breaking 2D quantum Hall topological phase is shown in red in the phase diagram of Fig. 2.

---

**Figure 1** | Topological phase transition. a, Six objects of different geometries can be grouped into three pairs of topologies. Each pair has the same topological invariant, known as its genus. b, Two waveguides formed by mirrors of different (right) and same (left) topologies. c, Frequency bands of different topologies cannot transition into each other without closing the frequency gap. A topological phase transition takes place on the right, but not on the left. d, Interfacial states have different connectivity along the waveguide. The magnitude of \(\Delta C\) equals the number of gapless interfacial modes and the sign of \(\Delta C\) indicates the direction of propagation.
A closed surface can be smoothly deformed into various geometries without cutting and pasting. The Gauss–Bonnet theorem\(^a\) of equation (1) below, which connects geometry to topology, states that the total Gaussian curvatures \(\mathcal{K}\) of a 2D closed surface is always an integer. This topological invariant, named genus \(g\), characterizes the topology of the surface; that is, the number of holes within. Examples of surfaces with different genus are shown in Fig. 1a.

\[
\frac{1}{2\pi} \int_{\text{surface}} \mathcal{K} \, dA = 2(1 - g) \tag{1}
\]

A two dimensional Brillouin zone is also a closed surface with the same topology of a torus due to its periodic boundary conditions (Fig. B1). Table B1 lists the definitions\(^b\) of Berry curvature and Berry flux with respect to Bloch wavefunctions in the Brillouin zone by comparing them to the familiar case of magnetic field and magnetic flux in real space. Integrating the Berry curvature over the torus surface yields the topological invariant known as the ‘Chern number’, which gives a measure of the total quantized Berry flux of the 2D surface. The Chern number can be viewed as the number of monopoles of Berry flux inside a closed surface, as illustrated in Fig. B1. An efficient way to calculate Chern numbers in discretized Brillouin zones is described in ref. 94.

Topological invariants can be arbitrary integers \((\mathbb{Z})\) or binary numbers \((\mathbb{Z}_2, \text{meaning } \mathbb{Z} \mod 2)\). Chern numbers are integers \((C \in \mathbb{Z})\) and the sum of the Chern numbers over all bands of a given system is zero.

Historically, the geometric phase was first discovered in optics by Pancharatnam\(^c\) prior to the discovery of the Berry phase\(^d\). The first experiments demonstrating the Berry phase were performed in optical fibres\(^e\).

**Box 1 | Topological invariant.**

A closed surface can be smoothly deformed into various geometries without cutting and pasting. The Gauss–Bonnet theorem of equation (1) below, which connects geometry to topology, states that the total Gaussian curvatures \(\mathcal{K}\) of a 2D closed surface is always an integer. This topological invariant, named genus \(g\), characterizes the topology of the surface; that is, the number of holes within. Examples of surfaces with different genus are shown in Fig. 1a.

\[
\frac{1}{2\pi} \int_{\text{surface}} \mathcal{K} \, dA = 2(1 - g) \tag{1}
\]

A two dimensional Brillouin zone is also a closed surface with the same topology of a torus due to its periodic boundary conditions (Fig. B1). Table B1 lists the definitions of Berry curvature and Berry flux with respect to Bloch wavefunctions in the Brillouin zone by comparing them to the familiar case of magnetic field and magnetic flux in real space. Integrating the Berry curvature over the torus surface yields the topological invariant known as the ‘Chern number’, which gives a measure of the total quantized Berry flux of the 2D surface. The Chern number can be viewed as the number of monopoles of Berry flux inside a closed surface, as illustrated in Fig. B1. An efficient way to calculate Chern numbers in discretized Brillouin zones is described in ref. 94.

Topological invariants can be arbitrary integers \((\mathbb{Z})\) or binary numbers \((\mathbb{Z}_2, \text{meaning } \mathbb{Z} \mod 2)\). Chern numbers are integers \((C \in \mathbb{Z})\) and the sum of the Chern numbers over all bands of a given system is zero.

Historically, the geometric phase was first discovered in optics by Pancharatnam prior to the discovery of the Berry phase. The first experiments demonstrating the Berry phase were performed in optical fibres.

**Figure B1 | Chern number as the number of Berry monopoles in momentum space.** A 2D Brillouin zone is topologically equivalent to a torus. The Chern number \((C)\) can be viewed as the number of monopoles \((\text{charges})\) of Berry flux inside a closed 2D surface. The arrows represent Berry curvature from the positive and negative charges. In a 3D Brillouin zone, these monopoles are Weyl points.

**Table B1 | Comparison of the Berry phase for Bloch wavefunctions and the Aharonov–Bohm phase.**

| Vector potential | A(r) | \(\mathcal{A}(k) = (\mathcal{A}(k)|\mathcal{V}_{j,l}(u(k))\) |
|------------------|-----|----------|
| Aharonov–Bohm phase | \(\oint A(r) \cdot dl\) | \(\oint A(k) \cdot dl\) |
| Magnetic field | \(B(r) = \nabla \times A(r)\) | \(\mathcal{F}(k) = \mathcal{V}_{j,l} \times \mathcal{A}(k)\) |
| Magnetic flux | \(\oint B(r) \cdot ds\) | \(\oint \mathcal{F}(k) \cdot ds\) |
| Magnetic monopoles | \# = \(\oint \oint B(r) \cdot ds\) | \(C = \frac{\oint \oint \mathcal{F}(k) \cdot ds}{2\pi}\) |

The Berry connection measures the local change in phase of wavefunctions in momentum space, where \(\mathcal{V}_{j,l}\) is a Hermitian operator. Similar to the vector potential and Aharonov–Bohm phase, Berry connection and Berry phase are gauge dependent (that is, \(u(k) \rightarrow u(k) + \nabla \phi(k)\)). The rest of the quantities are gauge-invariant. The Berry phase is defined only up to multiples of \(2\pi\). The phase and flux can be connected through Stokes’ theorem. Here, \(u(k)\) is the spatially periodic part of the Bloch function; the inner product of \(\mathcal{A}\) is done in real space. The one-dimensional Berry phase is also known as the Zak phase.

**Gyromagnetic photonic crystals**

Wang et al. were the first to realize the photonic analogue of the quantum Hall effect at microwave frequencies. Their experiment broke \(T\) by applying a uniform magnetic field on gyromagnetic photonic crystals, resulting in a single topologically protected edge mode that propagated around arbitrary disorder without reflection. Such single-mode one-way waveguides can be realized in coupled defect cavities, self-guide in free-standing slabs and have a robust local density of states. They have enabled novel device designs for tunable delays and phase shifts with unity transmission, reflectionless waveguide bends and splitters, signal switches, directional filters, broadband circulators and slow-light waveguides. Very recently, multimode one-way waveguides of large bulk Chern numbers \((|C| = 2, 3, 4)\) have been theoretically discovered by opening gaps of multiple point degeneracies simultaneously, thus providing even richer possibilities in terms of device functionalities.

Wang et al. based their experiments on a 2D square lattice photonic crystal comprising an array of gyromagnetic ferrite rods confined vertically between two metallic plates to mimic the 2D transverse magnetic (TM) modes. They also added a metal wall to the surrounding edges to prevent radiation loss into air (Fig. 3a). Without the external magnetic field, the second and third TM bands are connected by a quadratic point-degeneracy comprising a pair of Dirac cones. Under a uniform static magnetic field (0.2 T) that breaks \(T\), anti-symmetric imaginary off-diagonal terms develop in the magnetic permeability tensor \((\mu)\). The quadratic degeneracy breaks and a complete bandgap forms between the second and third bands, which both have non-zero Chern numbers. The red dispersion line in Fig. 3b is the gapless edge state inside the second bandgap, which has only positive group velocities at around 4.5 GHz. Numerical simulation results (Fig. 3c, top) verified that an antenna inside the waveguide can only emit in the forward direction in the bulk frequency gap. The experimental transmission data in Fig. 3d shows that the backwards reflection is more than five orders of magnitude smaller than the forwards transmission after propagating over only eight lattice periods. More importantly, there is no increase in the reflection amplitude even after the insertion of large metallic scatterers (Fig. 3c, bottom). Indeed, new one-way edge modes automatically form wherever a new interface is created, thus providing a path for light to circumvent the scatter. This is precisely...
Photons in an array of coupled resonators are similar to electrons 

Coupled resonators 

Photons in an array of coupled resonators are similar to electrons in an array of atoms in solids. The photon couplings between the resonators can be controlled to form topologically non-trivial frequency gaps with robust edge states. Researchers obtained the photonic analogues of the integer quantum Hall effect by constructing both static and time-harmonic couplings that simulate the electron’s behaviour in a uniform magnetic field. When the \( T \)-breaking is implemented by accurate time-harmonic modulations, unidirectional edge waveguides immune to disorder can be realized at optical frequencies.

In electronic systems, the first quantum Hall effect was observed in a 2D electron gas subject to an out-of-plane magnetic field. As illustrated in Fig. 4a, the bulk electrons undergo localized cyclotron motions, while the unidirectional edge electrons have an extended wavefunction. Again, the number of gapless edge channels equals the Chern number of the system. Here, the physical quantity describing the magnetic field is the vector potential, which can be written in the form \( \mathbf{A} = B \mathbf{k} \). An electron accumulates an Aharonov–Bohm (AB) phase of

\[
\phi = \oint \mathbf{A} \cdot dl
\]

after a closed loop (see Table B1). An electron going against the cyclotron motion acquires a phase of \(-\phi\) (dotted circle in Fig. 4a), so it has a different energy (from the electrons moving in solid circles). The spin degeneracy of electrons is lifted by Zeeman splitting. Although a photon does not interact with a magnetic field, it does acquire a phase change after passing through a closed loop. By carefully tuning the propagation and coupling phases, Hafezi et al. designed a lattice of optical resonators in which the photons acquire the same phase as the AB phase of electrons moving in a uniform magnetic field. This is different from a true quantum Hall topological phase, as \( T \) is not broken in their static and reciprocal resonator array. Thus, back-reflections are allowed because time-reversed channels always exist at the same frequencies. Nevertheless, Hafezi et al. were able to observe the edge states at near-infrared (1.55 \( \mu m \)) wavelengths in the first set of experiments performed on a silicon-on-insulator platform, and in a recent experiment also showed that robustness against particular types of disorder can still be achieved owing to the topological features of the phase arrangements.

**Box 2 | Time reversal symmetry.**

Symmetry considerations are crucial when determining the possible topological phases of a system. For example, the quantum Hall phase requires the breaking of time-reversal symmetry (\( T \)). On the other hand, in the recently discovered 2D and 3D topological insulators in electronics, \( T \)-symmetry is required to protect these topological phases characterized by \( \mathbb{Z}_2 \), topological invariants. For example, the 2D topological insulator, also known as the quantum spin Hall effect, allows the coexistence of counter-propagating spin-polarized gapless edge states. Without \( T \)-symmetry, however, these edge states can scatter into each other. The edge energy spectrum opens a gap and the insulator can continuously connect to trivial insulators, such as the vacuum. A large table of symmetry-protected topological phases have been theoretically classified\(^{23,24}\). These systems have robust interfacial states that are topologically protected only when the corresponding symmetries are present\(^{25}\).

Here we point out the fundamental difference in time-reversal symmetry between electrons and photons. A photon is a neutral non-conserved non-interacting spin-1 Boson that satisfies Maxwell’s equations, whereas an electron is a charged conserved interacting spin-1 Fermion that satisfies Schrödinger’s equation. Similar to Schrödinger’s equation, the lossless Maxwell’s equations at non-zero frequencies can be written as a generalized Hermitian eigenvalue problem:
Figure 3 | First experimental demonstration of the topologically protected one-way edge waveguide at microwave frequencies.

a. Experimental set-up for measuring the one-way edge state between the metal wall and the gyromagnetic photonic crystal confined between the metallic plates to mimic the 2D TM modes. The inset is a picture of the ferrite rods that constitute the photonic crystal of lattice period $a = 4$ cm.

b. The bandstructure of the one-way gapless edge state between the second and third bands of non-zero Chern numbers.

c. Simulated field propagation of the one-way mode and its topological protection against a long metallic scatterer.

d. The measured robust one-way transmission data of the edge waveguide.

is equivalent to the time-domain modulations that break $T$. This symmetry-breaking opens up protected band degeneracies in the Floquet bandstructure, thus forming a topologically non-trivial bandgap that contains protected gapless edge modes.

The idea of creating effective magnetic fields for neutral particles\(^5\) using synthetic gauge fields was first explored in optical lattices\(^3\). Very recently, similar gauge fields have also been studied in optomechanics\(^4\) and radiofrequency circuits\(^5\). Finally, although approximations such as ‘nearest-neighbour in space’ or ‘rotating-wave in time’ were adopted through the analysis of the systems described in this section, these higher order corrections do not fundamentally alter the topological invariants and phenomena demonstrated.

### Bianisotropic metamaterials

In bianisotropic materials ($\chi \neq 0$, Box 2)\(^5\), the coupling between electric and magnetic fields provides a wider parameter space for the realization of different topological phases. In particular, it has been shown that bianisotropic photonic crystals can achieve topological phases without breaking $T$ ($T$-invariant); thus, neither magnetism nor time-domain modulations are needed for the topological protection of edge states. Bianisotropic responses are known as ‘optical activity’ in chiral molecules and can also be designed in metamaterials.

Bianisotropy acts on photons in a similar way to how spin-orbit coupling acts on electrons\(^6\). In their inspiring theoretical proposal, Khanikaev et al. enforced polarization (‘spin’) degeneracy for photons by equating $\epsilon \pm \mu$ ($\epsilon = \mu$), so that the transverse electric (TE) and TM modes in two dimensions are exactly degenerate in frequencies.
When the pseudo-tensor $\chi$ is of the same form as the gyroelectric or gyromagnetic terms in $\varepsilon$ or $\mu$, then $\chi$ acts as a magnetic field on each polarization with opposite signs, without breaking $T$. This system can be separated into two independent 'spin' subspaces, in which quantum anomalous Hall phases exist with opposite Chern numbers.

Very recently, it was suggested that the $\varepsilon = \mu$ condition could potentially be relaxed. Indeed, in their experimental work, Chen et al. relaxed the material requirements for matching $z$ and $\mu$. They also realized a broadband effective biaxial response by embedding the $\varepsilon/\mu$-matched metamaterials in a metallic planar waveguide. These advances enabled them to observe the 'spin-polarized' edge transport at around 3 GHz.

Similar to the $T$-invariant resonator arrays in Fig. 4b and refs 9,16,38,42,43, the above metamaterial realizations also require strict conditions in order to decouple the two copies of 'spins'. In these cases, the requirements are on the accurate realization of the constitutive parameters during metamaterial manufacturing. The lack of intrinsic $T$-protected quantum spin Hall topological phase is one of the most fundamental differences between electronic and photonic systems, as discussed in Box 2. Finally, gapless surface states were also proposed to exist in a bulk hyperbolic metamaterial that exhibits biaxial responses.

**Quasicrystals**

Quasicrystals are aperiodic structures that possess spatial order. They also have frequency gaps and interfacial states. Quasicrystals can be constructed from the projections of periodic crystals in higher dimensions. Krauss et al. projected the 2D quantum Hall phase onto a 1D quasicrystal model containing a tunable parameter that is equivalent to the Bloch wavevector lost during the projection. Scanning this periodic parameter reproduced the full gapless frequency spectrum of the 2D quantum Hall phase; that is, the 0D edge mode frequency of the 1D quasicrystal continuously swept through the 1D bulk gap. The researchers fabricated 1D optical waveguide arrays to be spatially varying along $z$ according to the continuous tuning of this parameter. In their system, $z$ plays the role of time. They observed the edge state start from one edge of the waveguide array, merge into the bulk modes, then switch to the other edge of the array. Thus, light is adiabatically transferred in space from edge to edge. Going a step further, they proposed the potential realization of the quantum Hall phase in 4D using 2D quasicrystals.

**Weyl points and line nodes: Towards 3D topological phases**

2D Dirac points are the key bandstructures that led to the first proposal and experiments of the photonic analogue of the quantum Hall effect. For 3D topological phases, the key bandstructures are line nodes, 3D Dirac points and, more fundamentally, Weyl points. However, Weyl points have not yet been realized in nature. Recently, Lu et al. theoretically proposed the use of germanium or high-index glass for achieving both line nodes and Weyl points in gyroid photonic crystals at infrared wavelengths.

A line node is a linear line-degeneracy: two bands touch at a closed loop (Fig. 5a) while being linearly dispensed in the other two directions, thus making it the extension of Dirac cone dispersions in three dimensions. For example, $H(k) = v_k \sigma_i + v_y \sigma_j$ describes a line node along $k_y$. PT therefore protects both Dirac cones and line nodes. The line node bandstructure in Fig. 5b is found in a double gyroid (DG) photonic crystal with both $P$ and $T$. The surface dispersions of a line-node photonic crystal can be flat bands in controlled areas of the 2D surface Brillouin zone. When $PT$ is broken, a line node can either open up a gap or split into Weyl points. Figure 5c shows a phase diagram of the DG photonic crystals, where the line node splits into one or two pairs of Weyl points under $T$ or $P$ breaking, respectively.

A Weyl point is a linear point-degeneracy: two bands touch at a single point (Fig. 5d) while being linearly dispersed in all three directions. The low-frequency Hamiltonian of a Weyl point is $H(k) = v_y k_x \sigma_i + v_y k_y \sigma_j$ Diagonalization leads to the solution $\omega(k) = \pm \sqrt{(v_y k_x)^2 + (v_y k_y)^2 + (v_z k_z^2)}$. Because all three Pauli matrices are used in the Hamiltonian, the solution cannot have a frequency gap. The existence of the imaginary $\sigma_i$ term means that breaking $PT$ is a necessary condition for obtaining Weyl points. Weyl points are monopoles of Berry flux (Fig. 5d): a closed surface in a 3D Brillouin zone containing a single Weyl point has a non-zero Chern number of $\pm 1$. This means a single Weyl point is absolutely robust in 3D momentum space, as Weyl points must be generated and annihilated pairwise with opposite Chern numbers. When only $P$ is broken ($T$ preserved), the minimum number of pairs of Weyl points is two because $T$ maps a Weyl point at $k$ to $-k$ without changing its Chern number. When only $T$ is broken ($P$ preserved), the minimum number of pairs of Weyl points is one. The bandstructure in Fig. 5e, which contains the minimum of four Weyl points, is realized in a DG photonic crystal under $P$-breaking. Note that a Dirac point in three dimensions is a linear point-degeneracy between four bands, consisting of two Weyl points of opposite Chern numbers sitting on top of each other in frequency.

A photonic crystal that contains frequency-isolated Weyl points has gapless surface states. Consider the brown plane in the bulk Brillouin zone of Fig. 5f: it encloses either the top red Weyl point ($C = +1$) or the lower three Weyl points, depending on the choice of direction. Either way, this plane has a non-zero Chern number, similar to the 2D Brillouin zone in the quantum Hall case. Thus, any surface state with this particular fixed $k_y$ is gapless and unidirectional.

---

**Figure 4** | Quantum Hall phase of electrons in a magnetic field and of photons in coupled resonators exhibiting an effective magnetic field. 
---

(a) Cyclotron motions of electrons in a static magnetic field ($\mathbf{B2}$). The vector potential increases linearly in $y$. (b) A 2D lattice of photonic whispering-gallery resonators coupled through static waveguides. The horizontal coupling phases increase linearly in $y$. The two 'spins' of the whispering-gallery resonators are degenerate in the effective magnetic field. (c) A 2D lattice of photonic resonators consisting of two types of single-mode cavities. The nearest neighbours are coupled through time-domain modulations, with horizontal phases increasing linearly in $y$; this breaks $T$. (d) An array of helical photonic waveguides, breaking $z$ symmetry, induces harmonic modulations on any photons propagating through it.
We must be addressed. Moreover, the concepts and realizations of topological effects such as disorder and Anderson localization of those interfacial states between different topological mirrors will be studied. The immunity to disorder and localization in slow light and in coupled resonator optical waveguides. Unidirectional waveguides could decrease the power requirements of classical signals and improve coherence in quantum links. One-way edge states of \( T \)-breaking topological phases could be used as compact optical isolators. Edge states of \( T \)-invariant topological phases do not have reflection even when the system is reciprocal; thus, isolators may be unnecessary for photonic circuits comprising \( T \)-invariant topological phases. The realization of practical, topologically protected unidirectional waveguides at optical frequencies is currently the main challenge of this emerging field. Much like the field of topological insulators in electronics, topological photonics promises an enormous variety of breakthroughs in both fundamental physics and technological outcomes.

**Outlook**

The field of topological photonics has grown exponentially in recent years. Non-trivial topological effects have been proposed and realized across a variety of photonic systems at different wavelengths and in all three spatial dimensions. This Review has introduced the main concepts, experiments and proposals of topological photonics, focusing on 2D and 3D realizations. 1D examples are discussed in refs 66–72.

Over the coming years, we expect the discovery of new topological mirrors, phases and invariants, which could be classified with respect to different symmetries. The topological phases of interacting photons could be explored by considering nonlinearity and entanglement. Various topologically protected interface states between different topological mirrors will be studied. The immunity to disorder and Anderson localization of those interfacial states must be addressed. Moreover, the concepts and realizations of topological photonics can be translated to other bosonic systems such as surface plasmons, excitons, exciton–polaritons, phonons and magnons. Certain other robust wave phenomena can be explained through topological interpretations.

Technologically, the exploitation of topological effects could dramatically improve the robustness of photonic devices in the presence of imperfections. As a result, it will become easier to design robust devices. For example, designers will soon worry less about insertion loss and Fabry–Pérot noise due to back-reflections. Topologically protected transport could solve the key limitation from disorder and localization in slow light and in coupled resonator optical waveguides. Unidirectional waveguides could decrease the power requirements of classical signals and improve coherence in quantum links. One-way edge states of \( T \)-breaking topological phases could be used as compact optical isolators. Edge states of \( T \)-invariant topological phases do not have reflection even when the system is reciprocal; thus, isolators may be unnecessary for photonic circuits comprising \( T \)-invariant topological phases. The realization of practical, topologically protected unidirectional waveguides at optical frequencies is currently the main challenge of this emerging field. Much like the field of topological insulators in electronics, topological photonics promises an enormous variety of breakthroughs in both fundamental physics and technological outcomes.
