ABSTRACT: Is the production of the “AnchoisFert” organic fertilizer via the circular economy process based on omega-3 lipid extraction of milled anchovy fillet leftovers with citrus limonene followed by mild drying economically and technically viable? This study answers this question and identifies the main obstacles, chiefly of economic and organizational nature, to be overcome prior to commercialization of this new organic fertilizer. Along with non-variable and proven efficacy, successful competition with conventional organic and inorganic fertilizers requires affordable cost and regular supply. This, inter alia, requires to establish new and mutually beneficial relationship between bioeconomy firms and fish processing companies.

KEYWORDS: AnchoisFert; Fish waste; Green extraction; Limonene; Organic fertilizer

1. INTRODUCTION

We have recently reported the discovery of “AnchoisFert”, an highly effective organic fertilizer consisting of the solid residue of milled anchovy fillet leftovers extracted with biobased limonene.1 The process makes use of an agricultural by-product derived from the orange peel used both as lipid and vitamin D extraction solvent and as antimicrobial.2 In other words, it starts with an agricultural resource and ends benefiting agriculture (Scheme 1).

Scheme 1. The value chain actors involved in the production and utilization cycle of AnchoiFert.

In other words, the process closes the fishing material cycle for anchovy fishing fulfilling the main objective of the food “waste-to-value” approach by a new and efficient circular production loops in which fish biowaste is used as raw material for high value molecules and biomaterials.3

Numerous fertilizers derived from fish waste are commercially available, especially in the three North American countries.4 Nearly all of them, however, are derived from fish waste via chemical, enzymatic or thermal processing such as fish hydrolysate (requiring chemical or enzymatic hydrolysis),5 fish emulsion (requiring heating and skimming process) or fish silage (a liquid product made from fish parts liquefied by natural enzymes).

Extraction of fish oil from anchovy fillet leftovers with antimicrobial limonene affording “AnchoisOil”,6 does not require any chemical or enzymatic treatment of fish waste. Furthermore, limonene stabilizes fish waste against microbial spoilage.

As put it by Petrova and co-workers, the main obstacle to fish by-product utilization is of logistic nature because spoilage prevention requires quick transportation of fish waste to processing plants.6 Finally, as recently highlighted by Kruijssen and co-workers, little assessment of the impact of intervention efforts to tackle loss and waste in fish value chains has been published, with potential negative impacts on fisheries and consumers rarely considered.7

This study investigates the economic and technical feasibility of the “AnchoisFert” production via the circular economy process based on lipid extraction of anchovy fillet leftovers with citrus-derived limonene.1 We focus on Italy’s anchovy fillet industry, and identify the main obstacles to be overcome prior to commercialization of this new organic fertilizer. The results, however, are of general value. Along with proven efficacy, affordable cost and regular supply throughout the year are important factors to successfully compete with conventional organic and inorganic fertilizers. The effects of many organic fertilizers on crop yield, indeed, are often variable and slow,5 leading farmers to prefer chemical fertilizers regardless of environmental problems due to accumulation of inorganic acids, organic pollutants and heavy metals in groundwater8 and soil,9 as well as depletion of organic carbon in soil. On the other hand, the cost of chemical fertilizers is high and continuously growing making their use economically not viable for many farmers.10

2. RESULTS AND DISCUSSION

The ten most caught fish species account for 33% of global captures.12 Amounting to 11% of the world’s total landings, anchovy, and Peruvian anchoveta (Engraulis ringens) in particular, is by far the most caught fish species in the world. In 2018, 7.045 million tonnes of Peruvian anchoveta and 0.957 million tonnes of Japanese anchovy (Engraulis japonicus) were fished, with the ten most caught species accounting for

Anchovies are sold fresh or canned as canned fillets. Canned anchovies are prepared by a process of salting and ripening in sunflower or olive oil. During salting, marine salt diffuses into the fish lowering the water content and preventing the growth of spoilage bacteria. During ripening in oil, namely under anaerobic conditions which limit oxidation of polyunsaturated fatty acids abundant in anchovy fat, a number of biochemical processes driven by enzymes decompose proteins and fats, eventually affording soft anchovy fillets widely considered a gourmet speciality.

2.1 Italy’s anchovy industry. In Italy, production of European anchovy peaked in 2006 at more than 81,000 t, followed by a sharp reduction that reached a minimum of 29,664 t in 2013 (Figure 1). Since then, catches have risen again crossing in 2017 the 38,000 tonnes threshold (38,151).

![Figure 1. Italy’s landings of European anchovy (1950-2016) in tonnes (Reproduced from Ref.13, with kind permission).](image)

| Country | Catches (tonnes) |
|---------|------------------|
| Turkey  | 193,492          |
| Spain   | 49,982           |
| Russia  | 45,683           |
| Italy   | 37,511           |

| Table 1. Top 4 countries for European anchovy fished in 2015 (Reproduced from Ref.13, with kind permission). |

Each adult (1-2 years old) anchovy in this area of the Mediterranean sea weights ~13.2 g, with landings showing great annual variability between 1000 and >5000 tonnes.

To produce 1 kg of anchovy fillets preserved in oil 2.25 kg of anchovies are needed. This means that 0.55 kg of anchovy biowaste is available for producing AnchoisFert every kg of anchovy processed. Production of anchovy fillets preserved in oil in Italy amounted to 3,951 t in 2016, with 8 companies responsible for 80% of the national production (~ 3000 t), and the remainder 20% produced by smaller companies.

To dispose of anchovy fillet waste fish processing companies face an economic cost. In Sicily, for example, in 2021 the typical tariff paid for disposal currently stands at €0.2/kg, if the composting plant where the biowaste undergoes composting with other biological residues is within 100 km. Otherwise, a substantially higher tariff will be paid. At the aforementioned production rate of anchovy fillets amounting to 3,951 t in 2016, this means that Italy’s anchovy processing companies purchased 8,979 tonnes of fresh anchovies, 55% of which (4938 t) were disposed of as biowaste.

2.2 Organic fertilizers: cost and problems. The main problem with organic fertilizers limiting their uptake by farmers is their performance when compared to chemical fertilizers, since their effect on crop yield is often slow and variable. Furthermore, the price paid by farmers is often similar for both manure and chemical fertilizer. In Italy, for example, the price for both class of fertilizers currently stands at €0.72-0.76/kg, with the fertilizers packed in 25 kg bags sold at €18-19. Generally derived from manure obtained from intensive animal farming using large amounts of antibiotics, furthermore, most organic fertilizers significantly increase the abundance (and number) of antibiotic resistance genes in fertilized soil and crops and antibiotic resistance genes.

Finally, with the exception of digestates from agricultural energy crop digesters, organic fertilizers from biowaste fermentation and composting plants contain microplastics that progressively contaminate soil.

2.3. AnchoisFert production cost. The cost of manufacturing AnchoisFert (COM) is the sum (Eq.1) of the direct manufacturing cost (DMC), the fixed (indirect) manufacturing cost (FMC), and general expenses (GE):

\[
\text{COM} = \text{DMC} + \text{FMC} + \text{GE} \quad (1)
\]

The direct manufacturing cost is composed of the costs of raw material (CRM), operational labor (COL), utilities (CUT, including electricity and cooling water) and waste treatment (CWT). In the case of anchovy biowaste, the CRM is zero, whereas the extraction process does not generate any waste, zeroing also the CWT. The only expenses in the DMC voice are those of operational labor cost and of the electricity needed to recover the agrosolvent limonene.

Though expensive (price in late 2017 already exceeded $7/kg), the cost of limonene has little impact on the overall DMC because the biosolvent will be used for numerous extraction cycles, splitting its cost over said numerous extraction cycles. This has been shown in the case of rice bran oil extraction, and was found to be true also on the laboratory-scale extraction of AnchoisOil.

The FMC costs in Eq.1 are called “fixed” because they do not depend on production rate and are paid even if the process is halted. They simply consist of the equipment, maintenance depreciation, taxation and insurance (the latter paid to protect the company, generally 1-3% of fixed capital investment) expenses.
Finally, the general expenses (GE) are those needed to maintain the business, including administrative (salaries and other administration costs), sales (marketing, product delivery, and other costs related to sales), and research and development costs.  

Production of AnchoisFert (and AnchoisOil) via the agitated bed extraction (ABE) simply consists in placing a known mass of milled fish biowaste immersed in a known volume of limonene solvent inside an agitated tank. The scaled up process will employ the same convenient solid:solvent ratio (1.3:1) demonstrated on laboratory scale. The extraction takes place in 12 h only and does not require any heating, being carried out at room temperature starting from milled frozen anchovy biowaste mixed with cold limonene (kept at 4 °C).  

Among new and conventional extraction technologies such as ultrasound-assisted, pressurized liquid, and soxhlet extraction, as well as their combination, ABE was found to be by far the most economically convenient. The equipment ideally consists of two extractors, extract-solution tank, pump, evaporator, condenser, and recycled solvent tank. A second extraction vessel allows to carry out a continuous process in which while one of the vessels is under operation, the other one goes through the cleaning and recharging processes. Further supporting investment on industrial scale extraction, the COM in Eq.1 is inversely proportional to the extractor capacity, rapidly diminishing with the size of the extraction vessel (for example, it decreases by >40% when the extractor capacity is raised from 0.05 to 0.3 m³).  

Accurate estimates of the production costs in different parts of the world, with different taxation regimes, labor and electricity costs can be readily obtained via process simulation using a state of the art software affording the electricity costs and operational costs are due to labor and electricity to separate the oil from biobased solvent. Given the low production cost of both AnchoisOil and AnchoisFert, the main obstacles to be overcome prior to production and commercialization of these new bioproducts are of economic and organizational nature.

The interests of the supplier (the agri-food company) and the transformer (the bioeconomy company) engaged in the valorisation of agri-food residues must be aligned, ideally in the form of a jointly owned new firm.

The new bioeconomy will need both young managers and young technologists acquainted with the key enabling technologies of the bioeconomy, starting from the green extraction of natural products, as well as in integrating the activities of companies previously working in widely different markets.

Rather than waiting for the development of a suitable "regional environment for bioeconomy entrepreneurship [making available] various forms of formal and informal support", the new bioeconomy company should proactively act identifying and hiring the aforementioned new personnel, learning from the highly successful cases of many bioeconomy companies whose success goes back to the early 1900s.

One example is the pectin industry, whose prolonged success relies on the availability of good quality lemon peel from lemon juice companies. For several decades the industry supplied a relatively low amount (a few 10,000 tonnes per year) of highly profitable pectin to meet a slowly growing
global demand using dried lemon peel chiefly shipped from Argentina. When the global demand of pectin rose to today’s levels (70,000 tonnes, and counting), supply of dried lemon peel was no longer sufficient. Hence, the industry built several new plants close to citrus juice production plants using as raw material the fresh peel of orange, lime and lemon peel in place of dried lemon peel only.

A similar trend, we forecast in conclusion, will now impact the “fish bio refinery” using fish biowaste to produce high value end bioproducts (i.e., not ethanol or biogas) from readily degraded fish biowaste available in huge amount, though scattered amid many producers. Being a powerful antimicrobial (and antioxidant) already used to stop spoilage in fish, and enabling the concomitant production of a new marine oil and organic fertilizer residue, orange-derived limonene will play a crucial role in the new fish bio refinery starting from the most fished species across the seas. Its successful utilization in extracting an astaxanthin-rich marine oil from shrimp waste, indeed, has been already demonstrated.42

Actually, in conclusion, stabilization against microbial spoilage with limonene, and subsequent extraction of fish biowaste with the same biosolvent producing fish oil and organic fertilizers, is ideally suited for the Mediterranean fishing industry targeting the fresh consumption market.

A system for withdrawal and storage of fishery discards on the territory based on stabilization of discards immersed in cold limonene could be established at limited financial costs. Remarkably, the structure of Italy’s fishing industry with hundreds of vessels scattered over more than 8000 km of coast in hundreds of landing points, was lately identified as the main barrier to the full utilization of unwanted catches for the fishing operations in the Mediterranean Sea.43 Perhaps not surprisingly, in fact, Germany, France and Spain host selected companies that successfully produce fish oil, fishmeal and fish protein hydrolysates for the animal feed, cosmetic and nutraceutical markets at production sites (for example, in Boulogne-sur Mer and Concarneau in France, Artabra in Spain, Cuxhaven in Germany) located in close proximity to large fish processing plants.44 This ensures a nearly constant supply of high-quality fish by-products at relatively low cost.

A forthcoming study will explore the feasibility of the aforementioned model for Mediterranean fisheries.
