Abstract—We introduce a simple but effective technique in automatic hand gesture recognition using radar. The proposed technique classifies hand gestures based on the envelopes of their micro-Doppler signatures. These envelopes capture the distinctions among different hand movements and their corresponding positive and negative Doppler frequencies which are generated during each gesture act. We detect the positive and negative envelopes separately, and form a feature vector of their augmentation. We use the k-nearest neighbor (k-NN) classifier and Manhattan distance (L1) measure, in lieu of Euclidean distance (L2), so as not to diminish small but critical envelope values. It is shown that this method outperforms both low-dimension representations; micro-Doppler signature envelope.

Keywords—Hand gesture recognition; time-frequency representations; micro-Doppler signature envelope.

I. INTRODUCTION

Radar systems assume an important role in several areas of our daily life, such as air traffic control, speed enforcement systems, and advanced driver assistance systems [1–5]. Recently, radar has also become of increased interest for indoor applications. In particular, human activity monitoring radar systems are rapidly evolving with application that include gait recognition, fall motion detection for elderly care and aging-in-place technologies [4,5].

Over the past decade, much work has been done in human motion classifications which include daily activities of walking, kneeling, sitting, standing, bending, falling, etc. [6–18]. Distinguishing among the different motions is viewed as an inter-class classification [6–12], whereas the intra-class classification amounts to identifying the different members of the same class, e.g., classifying normal and abnormal gaits [13–18]. There are two main approaches of human motion classifications, namely those relying on handcrafted features that relate to human motion kinematics [7–8,13–15], and others which are data driven and include low-dimension representations [6,16], frequency-warped cepstral analysis [12], and neural networks [9,11,17,19].

In addition to classifying human motions, radars have been recently used for gesture recognition which is an important problem in a variety of applications that involve smart homes and human-machine interface for intelligent devices [19–25]. The latter is considered vital in aiding the physically impaired who might be wheelchair confined or bed-ridden patients. The goal is to enable these individuals to be self-supported and independently functioning. In essence, automatic hand gesture recognition is poised to make our homes more user friendly and most efficient through the use of contactless radio frequency (RF) sensors that can identify different hand gestures for instrument and household appliance control. The most recent project Soli by Google for touchless interactions is a testament of this emerging technology [25].

The same approaches employed for classifying human daily activities can be applied for recognition of hand gestures using the electromagnetic (EM) sensing modality. However, there is an apparent difference between micro-Doppler signatures of hand gestures and those associated with motion activities that involve human body. Depending on the experiment setup and radar data collection specs, micro-Doppler representations of hand gestures can be simple, limited to short time duration and small bandwidth, and are mainly characterized by their confined power concentrations in the time-frequency domain. On the other hand, the micro-Doppler signatures of body motions are intricate, of multi-component signals, span relatively longer time periods and assume higher Doppler frequencies.

In this paper, we present a method to discriminate five classes of dynamic hand gestures using radar micro-Doppler sensor. These classes are swiping hand, hand rotation, flipping fingers, calling and snapping fingers. We begin with several types of hand motions, and use the canonical angle metric to assess the subspace similarities constructed from their respective time-frequency distributions [26]. Based on the results, we group these motions into five most dissimilar classes. Two micro-Doppler features are extracted from the data spectrograms. They correspond to the upper and lower envelopes of the hand gesture micro-Doppler signatures. The two envelopes implicitly capture, for each motion, the positive-negative frequency differences, the time alignments and misalignments of the peak positive and negative Doppler frequencies, and the signature extent and occupancy over the joint time and frequency variables.

The work of Mr. Zhengxin is funded by the International Graduate Exchange Program of Beijing Institute of Technology, and was performed while he was a Visiting Scholar at the Center for Advanced Communications, Villanova University.
We compare the proposed approach with that based on PCA \cite{6,16} and on sparse reconstruction employing Gaussian-windowed Fourier dictionary \cite{19}. In the latter, the classifier was applied to hand gesture data showing signatures comprising rather detached power concentrated time-frequency regions. The experimental results applied to our measured data demonstrate that our proposed method outperforms the above two methods, and achieve a classification accuracy higher than 96%.

The remainder of this paper is organized as follows. In Section II, we present the extraction method of micro-Doppler signature envelopes and discusses the employed classifier. Section III describes the radar data collection and pre-processing of hand gestures. Section IV gives the experimental results based on the real data measurements. Section V is the conclusion of the paper.

II. HAND GESTURE RECOGNITION ALGORITHM

A. Time-frequency Representations

Hand gestures generate non-stationary radar back-scattering signals. Time-frequency representations (TFRs) are typically employed to analyze these signals in the joint-variable domains, revealing what is referred to as micro-Doppler signatures. A typical technique of TFRs is the spectrogram. For a discrete-time signal $s(n)$ of length $N$, the spectrogram can be obtained by taking the short-time Fourier transform (STFT)

$$ S(n,k) = \sum_{m=0}^{L-1} s(n+m) h(m) e^{-j2\pi mk/N}^2 $$

(1)

where $n = 0, \ldots, N-1$ is the time index, $k = 0, \ldots, K-1$ is the discrete frequency index, and $L$ is the length of the window function $h(.)$. It is noted that if the micro-Doppler signal can be modeled as a sum of frequency modulated signals, then the signal parameters can be estimated using maximum likelihood techniques \cite{27}. However, the micro-Doppler signal of the hand gesture does not conform to this model and, as such, spectrograms will be used for feature extractions. It is also noted that the signal $s(n)$ in equation (1) is considered as a non-stationary deterministic signal rather than a random process \cite{28}.

B. Extraction of the Micro-Doppler Signature Envelopes

We select features specific to the nominal hand gesture local frequency behavior and power concentrations. These features are the upper and lower envelope in the spectrograms. The envelopes attempt to capture, among other things, the local frequency behavior and power concentrations. These energies are then scaled to define the respective thresholds, $T_U$ and $T_L$.

$$ E_U(n) = \sum_{k=0}^{K-1} S(n,k)^2 $$

(2)

$$ E_L(n) = \sum_{k=K}^{L-1} S(n,k)^2 $$

(3)

These energies are then scaled to define the respective thresholds, $T_U$ and $T_L$.

$$ T_U(n) = E_U(n) \cdot \sigma_U $$

(4)

$$ T_L(n) = E_L(n) \cdot \sigma_L $$

(5)

where $\sigma_U$ and $\sigma_L$ represent the scale factors, both are less than 1. These scalars can be chosen empirically. However, an effective way for their selections is to maintain the ratio of the energy value to the threshold value constant over all time samples. For the upper envelope, this ratio can be computed by finding both values at the maximum positive Doppler frequency. Once the threshold is computed per equation (3), the upper envelope is then found by locating the Doppler frequency for which the spectrogram assumes equal or higher value. Similar procedure can be followed for the lower envelope. The upper envelope $e_U(n)$ and lower envelope $e_L(n)$, are concatenated to form a long feature vector $e = [e_U, e_L]$.

C. Classifier

We apply proper classifiers based on the envelope features extracted from the spectrograms. The $k$NN and Support vector Machine (SVM) are among the most commonly used classifiers in pattern recognition which are used in this paper. In particular, the $k$NN is a simple machine learning classification algorithm. For each test sample, the algorithm calculates the distance to all the training samples, and selects the $k$ closest training samples. Classification is performed by assigning the label that is most frequent among these samples \cite{30}. Clearly, the best choice of $k$ would depend on the data. In this work, $k$ is set to 1. Four different distance metrics are considered, namely, the Euclidean distance, the Manhattan distance \cite{31}, the Earth Mover’s distance (EMD) \cite{32} and the modified Hausdorff distance (MHD) \cite{33}.

SVM is a supervised learning algorithm \cite{34}. It exhibits clear advantages in nonlinear and high dimension problems.

III. HAND GESTURE SUBCLASSES

The data analyzed in this paper was collected in the Radar Imaging Lab at the Center for Advanced Communications, Villanova University. The radar system used in the experiment generates continuous wave, with carrier frequency and sampling rate equal to 25 GHz and 12.8 kHz, respectively.
The radar was placed at the edge of a table. The hand was approximately 20 cm away from radar at zero angle, and the arm remained fixed as much as possible during each gesture motion.

As depicted in Fig[1] The following 15 hand gestures were conducted: (a) Swiping hand from left to right, (b) Swiping hand from right to left, (c) Swiping hand from up to down, (d) Swiping hand from down to up, (e) Horizontal rotating hand clockwise, (f) Horizontal rotating hand counterclockwise, (g) Vertical rotating hand clockwise, (h) Vertical rotating hand counterclockwise, (i) Opening hand, (j) Flipping fingers, (k) Clenching hand, (l) Calling, (m) Swipe left with two fingers, (n) Snapping fingers, (o) Pinching index. Four persons participated in the experiment. Each hand gesture was recorded over 8 seconds to generate one data segment. The recording was repeated for 5 times. Each data segment contained 2 or 3 individual hand motions, and a 1 second time window is applied to capture the individual motions. As such, repetitive motions and associated duty cycles were not considered in classifications. In total, 755 segments of data for 15 hand gestures were generated.

As shown in Fig. 2, the spectrograms are converted to gray-scale images and vectorized with the size $100 \times 100$. In this case, the spectrograms are in agreement and consistent with each hand gesture. To mathematically confirm these resemblances, we consider sub-grouping the 15 similar motions generate similar signatures. To mathematically confirm these resemblances, we consider sub-grouping the 15 hand gestures using the Canonical correlation measure [26]. In this case, the spectrograms are converted to gray-scale images with the size $100 \times 100$, and then vectorized with the size $1 \times 10000$.

Define matrix $X$ contains $M$ vectorized images $S_i, i = 1, \cdots, M$ of a specific hand gesture,

$$X = [x_1 \mid x_2 \mid \cdots \mid x_M] \quad (6)$$

The $d$-dimensional subspace of a specific hand gesture can be obtained by taking PCA of $X$ [35]. Suppose $\Phi_1$ and $\Phi_2$ are two $d$-dimensional linear subspaces, the canonical correlations of the two subspaces are the cosines of principal angles, and are defined as [36]:

$$\cos \theta_i = \max_{u_i \in \Phi_1, \: v_i \in \Phi_2} u_i^T v_i \quad (7)$$

subject to $||v_i|| = ||v_j|| = 1, u_i^T u_j = v_i^T v_j = 0, i \neq j$. Let $U$ and $V$ denote unitary orthogonal bases for two subspaces, $\Phi_1$ and $\Phi_2$. The singular value decomposition (SVD) of $U^T V$ is

$$U^T V = P \Lambda Q \quad (8)$$

The canonical correlations are the singular values $\Lambda$, i.e., $\cos(\theta_i) = \lambda_i, i = 1, \cdots, d$. The minimum angle is used to measure the closeness of two subspaces. Table [1] shows the canonical correlations coefficients, from which we can clearly see the similarities between the different hand gestures; larger coefficient indicates the two hand gestures are more similar. The red part of the table indicates the coefficient exceeds 0.9, and the yellow part means the coefficient is over 0.85. According to the Table numbers, we group the 15 hand gestures into 5 Class. Class I is the gesture ‘Swiping hand’ which contains motions (a), (b), (c) and (d). Class II represents the gestures ‘Hand rotation’ which contains motions (e), (f),

Fig. 2. Spectrograms and corresponding envelopes of 15 different hand gestures.

Fig. 1. Illustrations of 15 different hand gestures.
(g) and (h). The gesture ‘Flipping fingers’, which involves motions (i) and (j), makes Class III. Class IV is the gesture ‘Calling’, which has motions (k), (l) and (m). The last Class V is the gesture ‘Snapping fingers’; it has motions (n) and (o). It is important to note that other similarity measures [37] can be applied, in lieu of the canonical correlation. However, we found the canonical correlation most consistent with the visual similarities.

### TABLE I. Canonical Correlations Coefficients

IV. EXPERIMENTAL RESULTS

In this section, all 755 data segments are used to validate the proposed method where 70% of the data are used for training and 30% for testing. The classification results are obtained by 1000 Monte Carlo trials. Three different automatic hand gesture approaches are compared with the proposed method. These are: 1) the empirical feature extraction method; 2) the PCA-based method [16]; 3) the sparse reconstruction-based method [19].

A. Empirical Feature Extraction Method

Three empirical features are extracted from the spectrograms to describe the hand gestures motions, namely the length of the event, the ratio of positive-negative frequency and the signal bandwidth. Fig. 3 is an example showing these handcrafted features.

![Empirical feature extraction](image)

Fig. 3. Empirical feature extraction.

1) **Length of the event** $T$: This describes the effective time duration to perform each hand gesture,

$$T = t_e - t_s$$  \hspace{1cm} (9)

where $t_s$ and $t_e$ represent the start time and the end time of a single hand gesture, respectively.

2) **Ratio of positive-to-negative peak frequencies** $R$: This feature is obtained by finding ratio of the maximum positive frequency value, $f_p$, and maximum negative frequency value, $f_n$,

$$R = \frac{|f_p|}{|f_n|}$$  \hspace{1cm} (10)

where $|\cdot|$ is the absolute function.

3) **Bandwidth** $B_w$: This is a measure of the signal effective width,

$$B_w = |f_p| + |f_n|$$  \hspace{1cm} (11)

The scatter plot of the above extracted features is shown in Fig. 4. Table II depicts the nominal behavior of these values over the different classes considered. When using $k$NN-L1 as the classifier, the recognition accuracy based on these features is only 68% with the confusion matrix shown in Table III.

![Scatter plot of three extracted empirical features](image)

Fig. 4. Scatter plot of three extracted empirical features.

### TABLE II. Nominal Behavior of Empirical Features over Different Classes

| Class  | Time | Ratio | Bandwidth |
|--------|------|-------|-----------|
| I      | large| moderate| moderate  |
| II     | large| moderate| small     |
| III    | small| large   | large     |
| IV     | small| small   | moderate  |
| V      | small| moderate| moderate  |

### TABLE III. Confusion Matrix Yielded by Empirical Feature Extraction Method

|   | I | II | III | IV | V |
|---|---|----|-----|----|---|
| I | 66.79% | 13.80% | 4.08% | 9.18% | 6.15% |
| II | 20.04% | 64.65% | 3.53% | 4.88% | 6.90% |
| III | 9.94% | 5.59% | 76.53% | 0.03% | 7.91% |
| IV | 19.04% | 6.74% | 0.65% | 71.79% | 1.78% |
| V  | 12.03% | 10.96% | 12.28% | 11.59% | 53.14% |

B. Proposed Envelope-based Method

As discussed in Section II, the extracted envelopes are fed into the $k$NN classifier, with different distance measures, and SVM classifier. The recognition accuracy are presented in Table IV. It is clear that the $k$NN classifier based on L1 distance achieves the highest accuracy, over 96%, followed by those employing the modified Hausdorff distance and the Euclidean distance. Different from other distances, the L1 distance attempts to properly account for small envelope values. The confusion matrix of the $k$NN classifier based on the L1 distance is shown in Table V from which we can find that Class III and Class IV are most distinguishable with the accuracy over 98%.

### TABLE IV. Recognition Accuracy with Different Types of Classifier

|       | Accuracy |
|-------|----------|
| SVM   | 83.07%   |
| kNN-L1| 95.23%   |
| kNN-L2| 93.87%   |
| kNN-EMD| 81.51%  |
| kNN-MHD| 93.95%  |
TABLE V. Confusion Matrix Yields by Envelope Method Based on kNN-L1 Classifier

|    | I     | II    | III   | IV    | V     |
|----|-------|-------|-------|-------|-------|
| I  | 95.23%| 3.17% | 0.14% | 1.46% | 0     |
| II | 3.03% | 95.39%| 0.01% | 0.06% | 1.51% |
| III| 0.07% | 0     | 99.01%| 0.28% | 0.64% |
| IV | 0.61% | 1.16% | 98.21%| 0.02% | 0     |
| V  | 0     | 2.31% | 2.61% | 2.83% | 92.25%|

TABLE VI. Confusion Matrix Yields by PCA-based Method with \( d = 30 \)

|    | I     | II    | III   | IV    | V     |
|----|-------|-------|-------|-------|-------|
| I  | 89.50%| 3.02% | 0.67% | 6.80% | 0.01% |
| II | 2.92% | 94.83%| 0     | 1.45% | 0.80% |
| III| 2.85% | 1.23% | 94.42%| 0     | 1.50% |
| IV | 5.24% | 0.25% | 1.37% | 93.14%| 0     |
| V  | 3.24% | 8.14% | 5.03% | 1.83% | 81.76%|

C. PCA-based Method

For the PCA-based method, each sample represents a spectrogram image of 100 × 100 pixels. The number of principal components \( d \) is determined by the eigenvalues. Fig. 5 shows how the classification accuracy changes with \( d \), with the recognition rate increases as \( d \) increases. However, there is no significant improvement of the recognition accuracy past \( d = 30 \). Table VI is the confusion matrix using 30 eigenvalues. Although the PCA method can achieve an overall accuracy of 92.71%, it is clearly outperformed by the proposed method.

D. Sparsity-based Method

The features used for this method are the time-frequency trajectories. Details of the sparsity-based method can be found in [19]. The trajectory consists of three parameters, namely the time-frequency position \((t_i, f_i), i = 1, \ldots, P \) and the intensity \( A_i \). \( P \) is the sparsity level that is set to 10 in this paper. Hence, each sample contains 30 features. The spectrograms of reconstructed signals and the \( P \) locations of time-frequency trajectory are plotted in Fig. 6 and Fig. 7. In the training process, the K-means algorithm is used to cluster a central time-frequency trajectory [38]. In the testing process, the \( k \)NN classifier based on the modified Hausdorff distance is applied to measure the distance between the testing samples and central time-frequency trajectories. The corresponding confusion matrix is presented in Table VII. The overall recognition accuracy was found to be only about 70% when applied to our data.

V. Conclusion

We introduced a simple but effective technique for automatic hand gesture recognition based on radar micro-Doppler signature envelopes. An energy-based thresholding algorithm was applied to separately extract the upper (positive) envelope and the lower (negative) envelope of the signal spectrogram. We used the canonical correlation coefficient to group 15 hand gestures into five different classes. The members of
each class have close signature behavior. The extracted envelopes were concatenated and input to different types of classifiers. It was shown that the kNN classifier based on L1 distance achieves the highest accuracy and provided over 96 percent classification rate. The experimental results also demonstrated that the proposed method outperformed the lower dimensional PCA-based method, the sparsity-based approach using Gaussian-windowed Fourier dictionary, and existing techniques based on handcrafted features.

### Table VII. Confusion Matrix Yielded by Sparsity-Based Method

|   | I   | II  | III | IV  | V   |
|---|-----|-----|-----|-----|-----|
| I | 71.72% | 11.36% | 1.45% | 11.74% | 3.73% |
| II | 10.95% | 81.29% | 2.57% | 0.28% | 4.91% |
| III | 7.40% | 2.10% | 83.63% | 0.69% | 6.18% |
| IV | 16.04% | 6.52% | 1.22% | 74.14% | 2.08% |
| V  | 6.65% | 15.05% | 9.96% | 10.02% | 58.32% |
