Abstract

We present a first theoretical study on interfacial magnetocrystalline anisotropy for Fe/MgAl$_2$O$_4$. This system has a very small lattice mismatch at the interface and therefore is suitable for realizing fully coherent ferromagnet/oxide interface for magnetic tunnel junctions (MTJs). On the basis of the density-functional theory, we calculate the interfacial anisotropy constant $K_i$ and show that this system has interfacial perpendicular magnetic anisotropy (PMA) with $K_i \approx 1.2$ mJ/m$^2$, which is a little bit smaller than that of Fe/MgO ($K_i \approx 1.5$–1.7 mJ/m$^2$). Second-order perturbation analysis with respect to the spin-orbit interaction clarifies that the difference in $K_i$ between Fe/MgAl$_2$O$_4$ and Fe/MgO originates from the difference in contributions from spin-flip scattering terms at the interface. We propose that the insertion of tungsten (W) layers into the interface of Fe/MgAl$_2$O$_4$ is a promising way to obtain huge interfacial PMA with $K_i \gtrsim 3$ mJ/m$^2$. 
Perpendicular magnetic anisotropy (PMA) is an essential property for ferromagnets (FMs) in magnetic tunnel junctions (MTJs) to realize nonvolatile magnetic random access memories (MRAMs) [1]. The PMA is beneficial for obtaining sufficiently high thermal stability and low critical current in spin-transfer-torque MRAMs (STT-MRAMs), in which current-induced spin-transfer torque is used for magnetization switching [1]. Although large PMA has been observed in several FMs such as $D_{022}^{22} \text{Mn}_3 \text{Ga}$ [2, 3], $D_{022}^{22} \text{Mn}_3 \text{Ge}$ [4, 5], $L_{10} \text{MnGa}$ [3], and $L_{10} \text{FePt}$ [6], MTJs with these FMs did not show sufficiently high tunnel magnetoresistance (TMR) ratios, which is another important requirement for MRAM applications. Therefore, interfacial PMA at interfaces between FMs and insulator barriers have attracted much attention mainly in MTJs consisting of Fe-based FMs and MgO barrier.

In addition to high TMR ratios [7–10], interfacial PMA has also been obtained in the MgO-based MTJs. By using thin CoFeB layers ($\sim 1.3$ nm), Ikeda et al. observed relatively large PMA at the interface of CoFeB/MgO/CoFeB MTJ [11]. In subsequent studies [12, 13], Koo et al. demonstrated that Fe/MgO has a larger interfacial PMA than that of CoFe(B)/MgO, in agreement with theoretical predictions [14, 15]. Furthermore, interfacial PMA has also been observed in the heterostructure composed of the Heusler alloy Co$_2$FeAl and MgO [16, 17]. The interfacial PMA is also advantageous for voltage-torque MRAMs [18], because high interfacial PMA gives low write error rates in voltage-driven magnetization switching.

The underlying mechanism of such interfacial PMA in Fe-based FM/MgO heterostructures has been discussed in several theoretical studies. By analyzing local density of states (DOS) and band structure in Fe/MgO, Nakamura et al. [19] clarified that the Fe $3d_{3z^2-r^2}$ state is distributed away from the Fermi level owing to their hybridization with the O $2p_z$ state, leading to interfacial PMA. Other studies [14, 20] also indicated the importance of this hybridization using different theoretical approaches. From a different point of view, the relation between PMA and orbital magnetic moment is another significant issue. A second-order perturbation theory by Bruno [21] revealed a proportional relation between magnetic anisotropy and anisotropy of orbital magnetic moment, which is the so-called Bruno relation. Several theoretical studies have discussed the applicability of the Bruno relation to various Fe-based heterostructures [15, 22, 23]. Moreover, by means of x-ray magnetic circular
dichroism (XMCD) measurements, Okabayashi et al. [24] showed that the interfacial PMA in Fe/MgO can be explained qualitatively by the Bruno relation. This relation gives valuable information for understanding the interfacial PMA in Fe-based FM/MgO heterostructures.

Although large interfacial PMA has been observed in Fe/MgO heterostructures, the lattice mismatch between Fe and MgO is rather large (∼4%), which is a drawback for practical applications. On the other hand, spinel oxide MgAl₂O₄ has a small lattice mismatch (<1%) with typical FMs such as Fe, Co₀.₅Fe₀.₅, and Co₂FeAl₀.₅Si₀.₅ [25]. Moreover, since the lattice constant of MgAl₂O₄ can be tuned by changing the Mg/Al composition rate, one can achieve good lattice matching with various FMs. Up to now, relatively high MR ratios have been observed in the MgAl₂O₄-based MTJs [25–28]. The interfacial PMA has also been obtained in some FM/MgAl₂O₄ heterostructures [29–31]. In particular, Koo et al. [29] reported that Fe(0.7 nm)/MgAl₂O₄ heterostructure has an interfacial PMA with interfacial anisotropy constant $K_i$ of 0.9–1.6 mJ/m², which is smaller than that of Fe/MgO heterostructure ($K_i$ ∼1.5–2.0 mJ/m²) with the same Fe thickness [12]. Possible reasons for such a difference in $K_i$ should be clarified; however, no theoretical study has addressed interfacial magnetocrystalline anisotropy in Fe/MgAl₂O₄.

In this work, we study interfacial magnetocrystalline anisotropy in Fe/MgAl₂O₄ by means of first-principles calculations based on the density-functional theory. We find that this system has interfacial PMA with $K_i$ ≈ 1.2 mJ/m². This value of $K_i$ is smaller than that calculated in Fe/MgO with similar barrier thickness ($K_i$ ≈ 1.5–1.7 mJ/m²), in agreement with the above-mentioned experimental results. To clarify the origin of such a difference in $K_i$, second-order perturbation analyses are carried out, which find that the smaller $K_i$ in Fe/MgAl₂O₄ is owing to a smaller positive contribution in $K_i$ from spin-flip electron scattering. We show that these results can be naturally understood from the features of the LDOSs and band structures in these systems. We finally propose an interfacial insertion of tungsten (W) layers to Fe/MgAl₂O₄ as a possible way to achieve a larger $K_i$. It is shown that such Fe/W/MgAl₂O₄ systems with 4–5 layers of W have large $K_i$ of $\gtrsim$ 3 mJ/m².

II. CALCULATION METHOD

We analyzed Fe/MgAl₂O₄(001) and Fe/MgO(001) by means of the density-functional theory (DFT) including the effect of spin-orbit interactions, which is implemented in the
Vienna \textit{ab initio} simulation program (VASP) \[32\]. We adopted the spin-polarized generalized gradient approximation (GGA) \[33\] for the exchange-correlation energy and used the projector augmented wave (PAW) potential \[34, 35\] to treat the effect of core electrons properly.

Figures 1(a) and 1(b) show the supercells of Fe(5)/MgAl\textsubscript{2}O\textsubscript{4}(9) and Fe(5)/MgO(5) used in this study, where each number in parentheses represents each layer number. Note that MgAl\textsubscript{2}O\textsubscript{4}(9) and MgO(5) have similar barrier thicknesses, which are suitable for comparison of interfacial magnetic anisotropy. As mentioned in Sec. I, the most striking feature of Fe/MgAl\textsubscript{2}O\textsubscript{4} is significantly small lattice mismatch between the electrode and the barrier; at the interface, two unit cells of bcc Fe with \(2a_{\text{Fe}} = 5.732\,\text{Å}\) can be well fitted to MgAl\textsubscript{2}O\textsubscript{4} with \(a_{\text{MgAl}_{2}\text{O}_{4}}/\sqrt{2} = 5.72\,\text{Å}\). Thus, we fixed the in-plane lattice constant \(a\) of Fe/MgAl\textsubscript{2}O\textsubscript{4} supercell to \(a = 2a_{\text{Fe}} = 5.732\,\text{Å}\). On the other hand, the lattice mismatch is relatively large in Fe/MgO, for which we used two supercells with different in-plane lattice constants \(a\): one is \(a = a_{\text{Fe}} = 2.866\,\text{Å}\), and the other is \(a = a_{\text{MgO}}/\sqrt{2} = 2.98\,\text{Å}\). In all of these supercells, we carried out structure relaxation, through which optimum atomic positions and the interfacial distance between the electrode and the barrier were determined. Here, we used a known fact that an interfacial atomic configuration where O atoms are on top of Fe atoms [see Figs. 1(a) and 1(b)] is energetically favored in both Fe/MgAl\textsubscript{2}O\textsubscript{4} and Fe/MgO \[36\]. The details of our structure relaxation are given in our previous paper \[40\].

In each optimized supercell, we calculated interfacial magnetocrystalline anisotropy \(K_i\) using the well-known force theorem \[41\]:

\[
K_i = \frac{(E_{[100]} - E_{[001]})}{2S},
\]

where \(E_{[100]}\) (\(E_{[001]}\)) is the sum of the eigenenergies of the supercell with the magnetization parallel to the [100] ([001]) direction, and \(S\) is the cross-sectional area of the supercell. Note that the factor 2 in the denominator reflects the fact that each supercell has two interfaces. In order to confirm whether the force theorem gives reliable results for the present systems, we also calculated \(K_i\) in the self-consistent-field (SCF) manner using the total energies instead of the sum of eigenenergies in Eq. \[41\]. In this paper, we represent a set of k-point numbers used for the calculations as \(N_x \times N_y \times N_z\), where \(N_x\), \(N_y\), and \(N_z\) are the numbers of k-point used for \(x\), \(y\), and \(z\) directions of supercells, respectively. Figure 2(a) shows the values of \(K_i\) in Fe/MgAl\textsubscript{2}O\textsubscript{4} as a function of the number of in-plane k-point \(N \equiv N_x = N_y\) obtained from
the force theorem and the SCF total-energy calculation, where \( N \) is fixed to 1 or 3. We see that the value of \( K_i \) is saturated for \( N \gtrsim 19 \) in all the four cases shown in the figure and that the saturated values are almost the same (\( K_i \sim 1.2 \text{ mJ/m}^2 \)). Similar saturations of \( K_i \) were also obtained in two Fe/MgO systems with \( a = a_{\text{MgO}}/\sqrt{2} \) and \( a = a_{\text{Fe}} \), as shown in Figs. 2(b) and 2(c), respectively. In both of these systems, \( K_i \) is saturated to \( \sim 1.2 \text{ mJ/m}^2 \) for \( N \gtrsim 37 \).

All these results indicate that the calculation using the force theorem and \( 19 \times 19 \times 1 \) (\( 37 \times 37 \times 1 \)) k-points is sufficient to accurately estimate \( K_i \) in Fe/MgAl\(_2\)O\(_4\) (Fe/MgO) \[42\]; in the following, we use such calculation conditions. From Eq. (1), we can easily see that positive (negative) \( K_i \) indicates the tendency toward perpendicular (in-plane) magnetic anisotropy. However, actual magnetic anisotropy is estimated by \( K_{\text{eff}}t = K_i + E_{\text{demag}}t \), where \( t \) is the effective thickness of Fe electrode and \( E_{\text{demag}}t \) represents magnetic shape anisotropy. The second term \( E_{\text{demag}}t \) always has a negative value, and therefore favors in-plane magnetic anisotropy. In the present work, we calculated \( E_{\text{demag}}t \) by summing up the magnetostatic dipole-dipole interaction between atomic magnetic moments \[41\] with the use of the Ewald-summation technique \[43\].

In addition to these calculations, we further carried out a detailed second-order perturbation analysis to understand magnetocrystalline anisotropy in Fe/MgAl\(_2\)O\(_4\) and Fe/MgO more deeply. By treating the spin-orbit interaction \( H_{\text{SO}} \) as a perturbation term, the second-order perturbation energy is expressed as

\[
E^{(2)} = \sum_k \sum_{n'\sigma'} \sum_{n\sigma} \frac{|\langle kn'\sigma'|H_{\text{SO}}|kn\sigma\rangle|^2}{\epsilon^{(0)}_{kn\sigma} - \epsilon^{(0)}_{kn'\sigma'}},
\]

(2)

\[
H_{\text{SO}} = \sum_i \xi_i L_i \cdot S_i,
\]

(3)

where \( \epsilon^{(0)}_{kn\sigma} \) is the energy of an unperturbed state \( |kn\sigma\rangle \) with wave vector \( k \), band index \( n \), and spin \( \sigma \). The index occ. (unocc.) on the summation means that the sum is over occupied (unoccupied) states of all atoms in the supercell \[44, 45\]. Note here that the state \( |kn\sigma\rangle \) can be expanded as \( |kn\sigma\rangle = \sum_{i\mu} c_{kn\mu}^i |i\mu\sigma\rangle \), where \( \mu \) is an atomic orbital at site \( i \) and \( c_{kn\mu}^i = \langle i\mu\sigma|kn\sigma\rangle \) \[44\]. In the spin-orbit interaction \( H_{\text{SO}} \), \( \xi_i \) is its coupling constant at site \( i \), and \( L_i (S_i) \) is the single-electron angular (spin) momentum operator. As the values of \( \xi_i \), we used \( \xi_{\text{Fe}} = 54.3 \text{ meV}, \xi_{\text{Mg}} = 47.5 \text{ meV}, \xi_{\text{Al}} = 10.8 \text{ meV}, \) and \( \xi_{\text{O}} = 24.3 \text{ meV} \) for Fe, Mg, Al, and O atoms, respectively. The Wigner-Seitz radius of each atom was set to \( r_{\text{Fe}} = 1.302 \text{ Å}, r_{\text{Mg}} = 1.524 \text{ Å}, r_{\text{Al}} = 1.402 \text{ Å}, r_{\text{O}} = 0.820 \text{ Å} \). All these values of spin-orbit coupling constants
and Wigner-Seitz radii are those listed in the pseudopotential files in VASP. We used wave functions and eigenenergies obtained in our DFT calculations as unperturbed states and energies in Eq. (2). The magnetocrystalline anisotropy energy within the second-order perturbation $E_{\text{MCA}}^{(2)} (\propto K_i)$ was calculated as $E_{\text{MCA}}^{(2)} = E_{[100]}^{(2)} - E_{[001]}^{(2)}$, where $E_{[100]}^{(2)}$ ($E_{[001]}^{(2)}$) is the energy for the magnetization along the [100] ([001]) direction obtained by Eq. (2). In the process of such an analysis, we can decompose $E_{\text{MCA}}^{(2)} = \sum_i E_{\text{MCA}}^i$ into four types of terms coming from different electron scattering around the Fermi level:

$$E_{\text{MCA}}^{(2)} = \sum_i (\Delta E_{\uparrow\to\uparrow}^i + \Delta E_{\downarrow\to\downarrow}^i + \Delta E_{\uparrow\to\downarrow}^i + \Delta E_{\downarrow\to\uparrow}^i).$$

(4)

Here, $\Delta E_{\uparrow\to\uparrow}^i$ ($\Delta E_{\downarrow\to\downarrow}^i$) originates from spin-conserving electron scattering between occupied and unoccupied majority-spin (minority-spin) states. On the other hand, $\Delta E_{\uparrow\to\downarrow}^i$ ($\Delta E_{\downarrow\to\uparrow}^i$) corresponds to spin-flip electron scattering from occupied majority-spin (minority-spin) states to unoccupied minority-spin (majority-spin) states. The details of these calculations are given in a previous paper [44]. As we show in the next section, differences in magnetocrystalline anisotropy between different systems can be explained naturally by these second-order perturbation analyses.

### III. RESULTS AND DISCUSSION

Table I shows the values of $K_i$, $E_{\text{demag}} t$, $K_{\text{eff}} t$, $\Delta M_{\text{orb},i}$, and $M_{\text{spin},i}$ for Fe/MgAl$_2$O$_4$ and Fe/MgO obtained in this study. Here, $\Delta M_{\text{orb},i}$ is the anisotropy of the interfacial Fe orbital magnetic moment and $M_{\text{spin},i}$ is the spin magnetic moment at interfacial Fe atoms. We see that Fe/MgAl$_2$O$_4$ has a positive $K_i$ of 1.192 mJ/m$^2$. Since this value exceeds the negative shape anisotropy ($E_{\text{demag}} t = -0.895$ mJ/m$^2$), this system has interfacial PMA ($K_{\text{eff}} t = 0.296$ mJ/m$^2 > 0$). Note that O layer is the termination layer of MgAl$_2$O$_4$, as mentioned in Sec. II. Thus, the interfacial hybridization between Fe 3$d_{3z^2-r^2}$ and O 2$p_z$ states plays a key role for the interfacial PMA of Fe/MgAl$_2$O$_4$ in the same way as Fe/MgO.

The values of $K_i$ and $K_{\text{eff}} t$ in Fe/MgAl$_2$O$_4$ are smaller than those in Fe/MgO. As mentioned in Sec. II, the relationship between magnetocrystalline anisotropy and anisotropy of the orbital magnetic moment provides important information on PMA in these systems. From Table I we find that both $K_i$ and $\Delta M_{\text{orb},i}$ of Fe/MgO with $a = a_{\text{MgO}} / \sqrt{2}$ are larger than those of Fe/MgAl$_2$O$_4$, which indicates that the Bruno relation ($K_i \propto \Delta M_{\text{orb},i}$) holds...
for these two systems. On the other hand, it seems that this relation is not applicable to Fe/MgO with $a = a_{Fe}$, because this system has a larger $K_1$ but a smaller $\Delta M_{orb,i}$ than Fe/MgAl$_2$O$_4$. Therefore, the following second-order perturbation analysis is required to deeply understand interfacial PMA in all of these systems.

In Fig. 3(a), we show the results of the second-order perturbation analysis for the magnetocrystalline anisotropy in Fe/MgAl$_2$O$_4$. We see that the interfacial Fe layer has the largest positive $E_{MCA}^i$, which provides the dominant contribution to the positive $K_1$ in this system. This indicates that Fe/MgAl$_2$O$_4$ has interfacial PMA. At the interfacial Fe layer (Fe1), the anisotropy due to minority-spin scattering ($\Delta E_{\downarrow\rightarrow\downarrow}^i$) provides the largest contribution. In order to understand this feature, we utilize the following simplified expressions for the local magnetocrystalline anisotropy [46]:

$$E_{MCA}^i \approx \Delta E_{\downarrow\rightarrow\downarrow}^i + \Delta E_{\uparrow\rightarrow\downarrow}^i,$$

$$\Delta E_{\downarrow\rightarrow\downarrow}^i = \xi_i^2 \sum_{u_{\downarrow},o_{\downarrow}} \frac{(|\langle u_{\downarrow} | L_z^i | o_{\downarrow} \rangle|^2 - |\langle u_{\downarrow} | L_x^i | o_{\downarrow} \rangle|^2)}{\epsilon_{u_{\downarrow}} - \epsilon_{o_{\downarrow}}},$$

$$\Delta E_{\uparrow\rightarrow\downarrow}^i = \xi_i^2 \sum_{u_{\downarrow},o_{\uparrow}} \frac{(|\langle u_{\downarrow} | L_z^i | o_{\uparrow} \rangle|^2 - |\langle u_{\downarrow} | L_x^i | o_{\uparrow} \rangle|^2)}{\epsilon_{u_{\downarrow}} - \epsilon_{o_{\uparrow}}},$$

where the meanings of $\Delta E_{\downarrow\rightarrow\downarrow}^i$ and $\Delta E_{\uparrow\rightarrow\downarrow}^i$ are the same as those in Eq. (4). Here, $\xi_i$ is the spin-orbit coupling constant, $L_{\alpha}^i$ ($\alpha = x, z$) is the local angular momentum operator at site $i$, and $|o_{\sigma}\rangle$ ($|u_{\sigma}\rangle$) is a local occupied (unoccupied) state with spin $\sigma$ and energy $\epsilon_{o_{\sigma}}$ ($\epsilon_{u_{\sigma}}$).

To derive these expressions, it is assumed that the occupied $d$ states in the majority-spin channel are located deep below the Fermi level. Therefore, we neglected $\Delta E_{\uparrow\rightarrow\uparrow}^i$ and $\Delta E_{\downarrow\rightarrow\uparrow}^i$ in Eq. (5) [compare with Eq. (4)]. Let us now focus on the local density of states (LDOS) of interfacial Fe atoms in Fe/MgAl$_2$O$_4$ shown in Fig. 3(b). From the inset of the figure, we find that the majority-spin states have quite small LDOS around the Fermi level. Thus, we can expect that the term $\Delta E_{\downarrow\rightarrow\downarrow}^i$ provides the dominant contribution in Eq. (5) in the case of Fe/MgAl$_2$O$_4$, which is consistent with our results shown in Fig. 3(a). In the previous paragraph, we mentioned that the Bruno relation holds in this system, which is reasonable because only $\Delta E_{\downarrow\rightarrow\downarrow}^i$ is taken into account in the derivation of the Bruno relation [17].

In order to obtain further information on the PMA in Fe/MgAl$_2$O$_4$, we analyzed wave-vector-resolved magnetocrystalline anisotropy and band structures of the supercell. Previous studies using this type of analysis on other ferromagnetic systems have shown that localized $d$ states around the Fermi level provide the dominant contribution to the magnetocrystalline
anisotropy \[19, 48–50\]. Figure 4(a) shows the in-plane wave vector \(k_\parallel\) dependence of \(\Delta E(k_\parallel) \equiv E_{[100]}(k_\parallel) - E_{[001]}(k_\parallel)\) \[51\]. Here, we plotted the case of \(k_z = 0\) because \(k_z\) dependence is very weak owing to long \(c\)-axis constant of the supercell. Note that \(K_1\) is proportional to the sum of \(\Delta E(k_\parallel)\) over all \(k_\parallel\) in the two-dimensional Brillouin zone. We see that large positive anisotropy is obtained around the \(\Gamma\) point, which provides the dominant contribution to the interfacial PMA in this system. We can naturally understand this behavior from the band structures of the supercell shown in Figs. 4(b) and 4(c). Actually, as seen from Fig. 4(c), the minority-spin bands around the \(\Gamma\) point have \(d_{zx}\) and \(d_{yz}\) orbital components near the Fermi level, leading to finite values of \(\langle d_{yz}, \downarrow |L_{z}^{i}|d_{zx}, \downarrow \rangle\) and \(\langle d_{zz}, \downarrow |L_{z}^{i}|d_{yz}, \downarrow \rangle\) included in the first term of the numerator of Eq. \(6\). Such a band structure is consistent with sharp peaks in the \(d_{yz}\)- and \(d_{zx}\)-orbital LDOSs in the minority-spin states around the Fermi level [see Fig. 3(b)].

We next discuss PMA in Fe/MgO to understand the difference with the case of Fe/MgAl\(_2\)O\(_4\). Figure 5(a) shows the results of the second-order perturbation calculations in Fe/MgO with \(a = a_{\text{MgO}}/\sqrt{2} = 2.98\ \text{Å}\). In this case, we obtained similar results with Fe/MgAl\(_2\)O\(_4\); anisotropy energy due to minority-spin scattering \(\Delta E_{i\Rightarrow\downarrow}^{i}\) at the interface provides the dominant contribution to the PMA. The structure of the LDOS at the interfacial Fe atoms is also similar to that of Fe/MgAl\(_2\)O\(_4\) [see Fig. 5(b)]; the majority-spin state has quite small LDOS around the Fermi level. In Fig. 5(a), a non-negligible difference with Fe/MgAl\(_2\)O\(_4\) is that the Fe/MgO has a larger positive spin-flip component \(\Delta E_{\uparrow\Rightarrow\downarrow}^{i}\) at the interfacial Fe atoms. To clarify the reason of this behavior, we show the \(k_\parallel\) dependence of \(\Delta E(k_\parallel)\) in Fig. 6(a). We find that positive anisotropy occurs mainly around the \(X\) point. Similar to the case of Fe/MgAl\(_2\)O\(_4\), \(d_{zx}\) and \(d_{yz}\) states in the minority-spin bands give finite values of \(\langle L_{z}^{i}\rangle\) as shown in Fig. 6(c), leading to positive \(\Delta E_{\downarrow\Rightarrow\downarrow}^{i}\). In addition, the majority-spin occupied \(d_{xy}\) band and minority-spin unoccupied \(d_{xx}\) band yield finite values of \(\langle d_{xx}, \downarrow |L_{z}^{i}|d_{xy}, \uparrow \rangle\), as seen from Figs. 6(b) and 6(c). This gives positive \(\Delta E_{\uparrow\Rightarrow\downarrow}^{i}\) following Eq. (7), which is the reason why this system has the non-negligible contribution from spin-flip scattering in the interfacial PMA.

We also carried out the same perturbation analysis on the other Fe/MgO with \(a = a_{\text{Fe}} = 2.866\ \text{Å}\), which provides valuable insight as explained below. Figure 7(a) shows the results of the calculations, in which we find a clear difference with those of Fe/MgAl\(_2\)O\(_4\) and also with those of Fe/MgO with \(a = a_{\text{MgO}}/\sqrt{2}\). Namely, at the interfacial Fe atoms,
the spin-flip component $\Delta E_{i \uparrow \Rightarrow \downarrow}$ is quite large and has a similar value as the spin-preserving component $\Delta E_{i \downarrow \Rightarrow \downarrow}$. This is the reason why the Bruno relation does not hold in this system as mentioned above. As far as we know, such an importance of spin-flip scattering in the Fe/MgO has not been pointed out so far. We can naturally understand the origin of this behavior by analyzing the LDOSs of interfacial Fe atoms shown in Fig. 7(b). As seen from the inset of the figure, the majority-spin state has a finite $d_{3z^2-r^2}$ LDOS around the Fermi level. Since these $d_{3z^2-r^2}$ states give finite values of $\langle d_{yz, \downarrow} | L_x^i | d_{3z^2-r^2, \uparrow} \rangle$, the large positive $\Delta E_{i \uparrow \Rightarrow \downarrow}$ can occur following Eq. (7) [52]. This is the reason for the magnitude relation $\Delta E_{i \downarrow \Rightarrow \downarrow} \approx \Delta E_{i \uparrow \Rightarrow \downarrow}$ in this system. This feature can also be confirmed by the $k_{\parallel}$ dependence of $\Delta E(k_{\parallel})$ and band structures of the supercell shown in Figs. 8(a)–8(c). The major difference with the case of $a = a_{\text{MgO}}/\sqrt{2}$ is that the majority-spin $d_{3z^2-r^2}$ band crosses the Fermi level around the $\Gamma$ point as shown in Fig. 8(b). Thus, the occupied $d_{3z^2-r^2}$ states in this band and the unoccupied $d_{yz}$ states in the minority-spin bands give finite values of $\langle d_{yz, \downarrow} | L_x^i | d_{3z^2-r^2, \uparrow} \rangle$ [see Figs. 8(b) and 8(c)], by which $\Delta E_{i \uparrow \Rightarrow \downarrow}$ becomes larger compared to the case of $a = a_{\text{MgO}}/\sqrt{2}$. An experimentally realized Fe/MgO heterostructure is expected to have an intermediate in-plane lattice constant between $a_{\text{Fe}} = 2.866$ Å and $a_{\text{MgO}}/\sqrt{2} = 2.98$ Å. Although the anisotropy energy from spin-flip scattering $\Delta E_{i \uparrow \Rightarrow \downarrow}$ is sensitive to the in-plane lattice constant, we can conclude from our results that Fe/MgO has a larger positive $\Delta E_{i \uparrow \Rightarrow \downarrow}$ than Fe/MgAl$_2$O$_4$. This is a possible explanation for the fact that the experimentally observed $K_i$ in Fe/MgO is larger than that in Fe/MgAl$_2$O$_4$.

IV. A WAY TO OBTAIN LARGER PMA

In order to obtain larger interfacial PMA for MTJs with MgAl$_2$O$_4$ barrier, we propose an insertion of thin W layers between MgAl$_2$O$_4$ and Fe electrode as shown in Fig. 9(a). The insertion of W layers at the interface of Fe/MgAl$_2$O$_4$ is based on the theoretical prediction of huge PMA in Fe/W(001) multilayer with the in-plane lattice constant of bulk bcc-Fe [53]. Experimentally, Matsumoto and his co-workers confirmed the large change of magnetic anisotropy from negative to positive by reducing the W layer thickness in the Fe/W(001) multilayer, where the in-plane lattice constant of W approaches from that of bulk W to that of bulk Fe [53, 54]. Motivated by these theoretical and experimental results, we examined the possibility that the insertion of thin W layers into the interface of Fe/MgAl$_2$O$_4$
with the in-plane lattice constant of bcc-Fe can enhance the interfacial PMA in this junction. In Fig. 9(b), we show the calculated values of $K_i$ in Fe/W(n)/MgAl$_2$O$_4$(001) and Fe/W(n)/MgO(001). As in-plane lattice constants, we adopted $a = 2a_{Fe}$ for the MgAl$_2$O$_4$-based junction and $a = a_{Fe}$ and $a = a_{MgO}/\sqrt{2}$ for the MgO-based junction. As can be seen in Fig. 9(b), Fe/W(3–5)/MgAl$_2$O$_4$ and Fe/W(4–5)/MgO with $a = a_{Fe}$ have large positive $K_i$, indicating that the insertion of W layers significantly enhances the PMA in these junctions. Note that such a large enhancement was not obtained in very thin W cases ($n = 1–2$). Thus, at least 3 layers of W are required for enhancing PMA. On the other hand, Fe/W(n)/MgO with $a = a_{MgO}/\sqrt{2}$ shows a negative or small $K_i$ for any layer number of W up to $n = 5$, which means that the insertion of W layers degrades the interfacial PMA in this junction because of the lattice mismatch between Fe and MgO. These results are consistent with those of Fe/W multilayers in Ref. [53]. We can conclude that the insertion of W layers into the interface of Fe/MgAl$_2$O$_4$ is a promising way to obtain huge PMA owing to the good lattice matching between Fe and MgAl$_2$O$_4$, indicating the advantage of MgAl$_2$O$_4$ as compared with MgO. Perhaps it might be even better to use W layers as underlayers of Fe/MgAl$_2$O$_4$, because the interfacial insertion of non-magnetic metals between FMs and insulator barriers tends to decrease TMR ratios of MTJs. However, further analysis for the PMA in such a system is beyond the scope of this study and will be addressed in our future work.

From the second-order perturbation analysis, we found that the large PMA in the Fe/W/MgAl$_2$O$_4$ multilayer is mainly attributed to perturbation processes through unoccupied majority-spin states ($\Delta E_{↓→↑}^i$ and $\Delta E_{↑→↑}^i$) of the middle layer W atoms. Figures 10(a)–10(d) show the projected LDOSs of middle layer W atoms in Fe(5)/W(3)/MgAl$_2$O$_4$(9) and Fe(5)/W(3)/MgO(5) ($a = a_{Fe}$ and $a = a_{MgO}/\sqrt{2}$). As can be seen in Figs. 10(a) and 10(c), there are large unoccupied $d_{xy}$ and $d_{yz}$ ($d_{zx}$) states just above the Fermi level, when the in-plane lattice constant corresponds to that of bcc Fe ($a = a_{Fe}$). Because W is a transition metal element with less-than-half $d$ electrons, it has unoccupied majority-spin $d$ states. These unoccupied majority-spin states provide a considerable contribution to the PMA through the second-order perturbation of the spin-orbit interaction between unoccupied majority-spin states and occupied states in both the spin channels. In the present case, the matrix elements $\langle d_{xy}, ↑ | L_2^z | d_{x^2−y^2}, ↑ \rangle$ and $\langle d_{yz}, ↑ | L_2^z | d_{3z^2−r^2}, ↓ \rangle$ show positive contributions to the PMA of Fe(5)/W(3)/MgAl$_2$O$_4$(9) and Fe(5)/W(3)/MgO(5) ($a = a_{Fe}$) in the perturbation processes.
V. SUMMARY

We theoretically investigated interfacial magnetocrystalline anisotropy in Fe/MgAl$_2$O$_4$, which has a potential applicability to spintronic devices because of its quite small lattice mismatch at the interface. By means of the density-functional theory, we calculated interfacial anisotropy constant $K_i$ of this system and compared it with those of two Fe/MgO systems with different in-plane lattice constants. We found that Fe/MgAl$_2$O$_4$ has interfacial perpendicular magnetic anisotropy (PMA) with $K_i \approx 1.2$ mJ/m$^2$, which is slightly smaller than those of the Fe/MgO systems. By carrying out the second-order perturbation calculations on the PMA in combination with detailed analyses of the LDOSs and band structures, we clarified that the smaller $K_i$ in Fe/MgAl$_2$O$_4$ is owing to the smaller positive anisotropy energy from spin-flip electron scattering. We finally proposed insertion of tungsten (W) into the interface of Fe/MgAl$_2$O$_4$ as a possible way to obtain larger interfacial PMA. We showed that such insertion enhances $K_i$ of Fe/MgAl$_2$O$_4$ to $\gtrsim 3$ mJ/m$^2$.

[42] Note that the required number of in-plane k-point in Fe/MgAl\textsubscript{2}O\textsubscript{4} is about half that of Fe/MgO, because the in-plane lattice constant of Fe/MgAl\textsubscript{2}O\textsubscript{4} is about twice as that of Fe/MgO.

[51] As mentioned in Sec. II, the in-plane lattice constant of Fe/MgAl$_2$O$_4$ supercell is approximately twice as those of Fe/MgO supercells. Thus, we plotted $\Delta E(k_{||})/4$ for reasonable comparison with Fe/MgO cases shown in Figs. 6(a) and 8(a).

[52] Note that the small values of the energy difference $\epsilon_{u\downarrow} - \epsilon_{o\uparrow}$ between the unoccupied $d_{yz}$ ($d_{zx}$) and occupied $d_{3z^2-r^2}$ states enhances the value of $\Delta E_{\uparrow\downarrow}^i$.
