ABSTRACT

Three-wave mixing is a key process in superconducting quantum information processing, being involved in quantum-limited amplification and parametric coupling between superconducting cavities. These operations can be implemented by superconducting nonlinear asymmetric inductive element (SNAIL)-based devices that present a Kerr-free flux-bias point where unwanted parasitic effects, such as Stark shift, are suppressed. However, with a single flux-bias parameter, these circuits can only host one Kerr-free point, limiting the range of their applications. In this Letter, we demonstrate how to overcome this constraint by introducing the gradiometric SNAIL, a doubly flux biased superconducting circuit in which both effective inductance and Kerr coefficient can be independently tuned. Experimental data show the capability of the gradiometric SNAIL to suppress the Kerr effect in a three-wave mixing parametric amplifier over a continuum of flux bias points corresponding to a 1.7 GHz range of operating frequencies.

Superconducting circuits for quantum computation rely on Josephson tunnel junctions (JTJs) to implement nonlinear operations. For microwave signals at frequencies significantly lower than its plasma frequency, a JTJ acts as a nonlinear inductance whose response can be tuned in situ when a proper phase bias is applied across it. This is achieved by threading a magnetic flux through a superconducting loop involving the JTJ. More generally, a one-loop JTJ circuit with two leads attached constitutes a dipole that can be characterized by a tunable potential energy

\[ U(\phi) = \sum_{n=2}^{\infty} \frac{c_n(\Phi)}{n!} (\phi - \phi_0)^n, \]

where \( \phi \) is the gauge-invariant phase drop across the dipole, \( \Phi \) is the magnetic flux threaded through the loop, \( c_n(\Phi) = d^n U / d\phi^n \big|_{\phi_0} \) are Taylor expansion coefficients, and \( \phi_0 \) is the value of \( \phi \) that minimizes the potential energy. In expression (1), the coefficients \( c_n(\Phi) \) can be varied with flux in order to select a particular combination of linear and nonlinear effects. For instance, a superconducting dipole can be configured to offer a certain value of inductance \( \propto 1/c_2(\Phi) \), three-photon processes \( \propto c_3(\Phi) \), or four-photon process \( \propto c_4(\Phi) \) efficiencies. Such tunable dipoles have been implemented with rf-SQUIDs and with superconducting nonlinear asymmetric inductive element (SNAIL)2 employed for three-wave3-5 and four-wave mixing6 operations.

The SNAIL, represented on the left of Fig. 1(a), is realized by shunting an array of typically three identical JTJs, each one with Josephson energy \( E_J \), with a single JTJ with Josephson energy \( \alpha E_J \) with \( \alpha < 1/3 \). This constraint is required to ensure that the potential energy (1) has a single minimum in the interval \([-3\pi, 3\pi]\) for every value of an external flux \( \Phi \). The application of a flux-bias to a SNAIL makes it a versatile superconducting dipole capable of implementing different combinations of nonlinear effects: three-wave mixing amplification with suppressed Kerr constant \( K(c_2, c_3, c_4) \)

\[ K = \frac{c_2}{c_3}, \]

or four-wave-mixing with reversed Kerr constant. However, once a flux-bias point is selected, for instance, to obtain a desired value of the Kerr constant, the values of \( c_2 \) and \( c_3 \) will be fixed as a consequence, restricting the range of possible applications of a SNAIL-based circuit. Is it possible to decouple the flux dependencies of two parametric processes and, for instance, achieve three-wave mixing amplification with suppressed Kerr constant at any desired value of the resonance frequency?

In this Letter, we show how to implement this type of tunability with a doubly flux biased Josephson device, namely, the Gradiometric SNAIL (G-SNAIL). Strongly influenced by two recent superconducting circuits biased by two in situ magnetic fluxes,7 our device is capable of selecting a combination of two different parametric processes thanks to an additional tuning knob with respect to single-flux biased devices. For example, a G-SNAIL can implement the same linear
response $c_z$ for different combinations of bias fluxes, corresponding to different combinations of $c_z$ and $c_x$. In particular, a G-SNAIL could be capable, for instance, of keeping the Kerr constant $K(c_z, c_x, c_y)$ suppressed while varying $c_z$. We want to clarify that the symmetric $r$-SQUID first demonstrated the possibility to doubly flux bias a Josephson device for 3W applications at microwave frequencies. However, it was operated as the building block of a traveling wave parametric amplifier (TWPA) and lacked a quantitative demonstration of independent tuning of two parametric processes. With the G-SNAIL, we propose a minimal and more compact realization of a similar idea in a resonant parametric amplifier.

A G-SNAIL is obtained by shunting a SNAIL with another small junction with Josephson energy $E_J$, forming the circuit on the right of Fig. 1(a). This produces a dipole with a central array of three JTJs with energy $E_J = \Phi_0 I_c / 2\pi$ [purple junctions in Fig. 1(a)], shunted by two JTJs with energy $E_{J2}$ [blue junctions in Fig. 1(a)]. Here, $\Phi_0$ is the magnetic flux quantum, and $I_c$ is the critical current of a JTJ in the central array of the G-SNAIL. The two loops formed by this configuration can then be independently flux biased. This configuration is equivalent to a symmetric dc-SQUID shunted by an array of three JTJs. However, a G-SNAIL with a symmetric layout can be more efficiently and independently flux-biased by two symmetrically placed on-chip current lines, as discussed later in this paper.

To derive the potential energy for a G-SNAIL, we choose the convention in which the phase variable $\phi$ is equal to the phase drop across the central array [purple junctions in Fig. 1(a)]. Consequently, the magnetic fluxes $\Phi_{J(2)}$, respectively, threaded to the left and right loops of the G-SNAIL, will only appear in the contributions of the two small junctions to the total potential energy. After applying standard trigonometric transformations to separate the cos $\phi$ and sin $\phi$ contributions arising from the flux-tunable terms, the G-SNAIL potential energy can be expressed as

$$U(\phi) = -3 \cos \frac{\phi}{3} - [b_1(\phi_1, \phi_2) \cos \phi + b_2(\phi_1, \phi_2) \sin \phi],$$

where $\phi_{J(2)} = 2\pi \Phi_{J(2)}/\Phi_0$ and $b_{1,2}$ are flux-tunable bias parameters that weight even and odd order nonlinear terms. Introducing $\phi_{\pm} = (\phi_1 \pm \phi_2)/2$, we can define the effective quantities

$$x_{\text{eff}} \equiv \Phi_0 \cos \phi_{\pm}, \quad \phi_{\text{eff}} \equiv \phi_{\pm} + \pi [1 - \text{sgn}(\cos \phi_{\pm})],$$

where $x_{\text{eff}}$ acts as an effective, in situ tunable $x$ of a SNAIL controlled by the flux bias parameter $\phi_\pm$, and with a maximum value $x_0$, which is the maximum of $\phi_1$ and $\phi_2$. Making use of the definitions (3), G-SNAIL bias parameters can be expressed as $b_1 = x_{\text{eff}} \cos \phi_{\text{eff}}$ and $b_2 = x_{\text{eff}} \sin \phi_{\text{eff}}$. Consequently, G-SNAIL potential energy (2) can be re-expressed as

$$U(\phi) = -3 \cos \frac{\phi}{3} - x_{\text{eff}} \cos \phi_{\text{eff}} - x_{\text{eff}} \sin \phi_{\text{eff}}.$$

which is formally equivalent to the potential energy of a SNAIL. This one-to-one correspondence clarifies how a G-SNAIL behaves as a SNAIL with tunable $x$, thus can be employed in every SNAIL-based application for increased versatility. The bias parameters $b_1$ and $b_2$ can be defined for a SNAIL as well, where $x_{\text{eff}} = x_0$ and $\phi_{\text{eff}} = 2 \pi \Phi_{\text{eff}}/\Phi_0$, where $\Phi_0$ is the flux threaded to the loop in the right image of Fig. 1(a). As represented in Fig. 1(b), the two bias knobs of the G-SNAIL allow us to choose values for $b_1$ and $b_2$ on a 2D space thanks to the tunable $\cos \phi_{\text{eff}}$ term in the $\phi_{\text{eff}}$, which enables an independent tuning of even and odd order Josephson nonlinearities in the potential energy (4). Instead, for a SNAIL, with an $x$ set by fabrication, the parameters are constrained to lie on the circumference of the circle in Fig. 1(b) and cannot be independently chosen. This peculiarity of our device provides additional flexibility for tuning of expansion coefficients $c_x$ in expression (1). In a realistic G-SNAIL, where the Josephson energies of the small JTJs in the right image of Fig. 1(a) are never perfectly matched, $x_{\text{eff}}$ cannot be tuned all the way down to zero. This effect is not detrimental as usually SNAILs are operated at values of $x$ not too close to zero.

When a G-SNAIL is configured with a symmetrical layout as in the right image of Fig. 1(a), the phase biases $\phi_{\pm}$ are proportional to $i_{\pm} = i_1 \pm i_2$, where $i_{1,2}$ are the bias currents in Fig. 1(c). The choice of a symmetrical layout then simplifies the control of $x_{\text{eff}}$ and $\phi_{\text{eff}}$, which can be independently set by $i_{\pm}$, as can be obtained from Eq. (3).

To demonstrate the capability of G-SNAILs to suppress the Kerr constant in a three-wave mixing parametric amplifier, we build an array of 20 G-SNAILs embedded in a $\lambda/2$ microstrip resonator [Fig. 1(c)], which is strongly coupled to a probe port (left) and weakly coupled to a pump port (right). The resonator would have a bare resonance frequency $\omega_0/2\pi = 15.61$ GHz, when substituting the array of
G-SNAILs with a short circuit, and a characteristic impedance $Z_0 = 50 \Omega$. The value for $\alpha_0$ was extracted from a resonance frequency fit as a function of bias phases $\varphi_\pm$, as explained below. These quantities are obtained considering a lumped-element model of the resonator in Fig. 1(c), where the array of G-SNAILs is in series with the equivalent linear inductance of the resonator $L_e = Z_0/\alpha_0$. The experimental device is fabricated with an aluminum-based single-step deposition, where the Al/AlO$_x$/Al JTJs are realized with a Dolan bridge technique. The bottom layer is deposited with a nominal thickness of 35 nm, while the top layer is deposited with a nominal thickness of 120 nm. From fitting resonance frequency data with the model discussed below, we extract a critical current for the big JTJs in the central array of the G-SNAIL $I_c$. The top panel of Fig. 1(d) shows a scanning electron microscopy (SEM) image of the center of the $\lambda/2$ resonator with the embedded array of 20 G-SNAILs and the two flux lines, one for each side of the array. The bottom panel of the same figure shows a magnified picture of a portion of the array, where each G-SNAIL is made by an array of three big JTJs (purple) in the center shunted by two small JTJs (blue) on each side.

As a first demonstration of the doubly flux bias capability of our device, we perform small-signal 1-tone spectroscopy at the signal port with a vector network analyzer for many combinations of the bias phases $\varphi_\pm$. Then, we extract the resonance frequency with a tool for the analysis of microwave resonators.\textsuperscript{12} The resonance frequency predicted by theory reads
\begin{equation}
\omega_{k\pm}(\varphi_+, \varphi_-) = \frac{\omega_0}{\sqrt{1 + M \gamma_2/\gamma_1(\varphi_+, \varphi_-)}},
\end{equation}
where $\omega_0$ is the bare resonator frequency, $\gamma_1 = L_1/L_e$ is the ratio between the linear inductance $L_1 = \Phi_0/(\pi L_0)$ of a big junction in the central array of the G-SNAIL and the equivalent inductance $L_0$ of the bare resonator, and $\gamma_2$ is the second-order derivative of G-SNAIL potential energy (2) evaluated at the value $\varphi_0$ that minimizes the potential. Resonance frequency experimental data [Fig. 2(a)] acquired by varying $\varphi_\pm$ are compared to numerical simulations [Fig. 2(b)] based on expression (5). The simulations are performed using a set of parameters extracted with a nonlinear least-square fit of the experimental data. In Fig. 2(c), a comparison between the measured (markers) and simulated (lines) resonance frequency is presented for $\varphi_+/2\pi = 0.06$ (purple markers, solid lines) and for $\varphi_+/2\pi = 0.63$ (orange markers, dashed lines) while varying $\varphi_-$. From the comparison figure, it is possible to notice how the two selected curves intersect in two specular points, highlighted with dark blue circles. This is a first demonstration of the advanced tuning capabilities of our device: at each intersection point in Fig. 2(c), both curves have the same frequency but are associated with different combinations of $\gamma_1$ and $\gamma_2$ nonlinear expansion coefficients of the G-SNAIL potential energy (2).

We can now characterize the tunability of G-SNAILs' nonlinear properties, in particular, the Kerr coefficient $K$. For this sake, we measure the frequency Stark shift $\Delta_{\text{Stark}}(\varphi_+, \varphi_-)$ as a function of the average number of photons populating the resonator $n$ by fixing the bias phases and performing 1-tone spectroscopy with a vector network analyzer while sweeping the probe tone power. The correspondence between the probe tone power and $n$ is calibrated from room temperature measurements of input line attenuation and resonance frequency and quality factors of the device\textsuperscript{12} extracted from small signal measurements. From this type of measurement, for each combination of $\varphi_+, \varphi_-$, $K$ can be extracted as the frequency Stark shift per photon $d\Delta_{\text{Stark}}/dn|_{n=0}$.

Stark shift experimental data are presented in Figs. 3(a) and 3(b) for two fixed values of $\varphi_-$ over many values of $\varphi_+$. For each value of $\varphi_-$, the figures show positive, negative, or zero Stark shift as a function of $\varphi_+$. Zero Stark shift points, where all the curves in Figs. 3(a) and 3(b) intersect, can be identified as Kerr-free points.\textsuperscript{12} In Fig. 3(a), for $\varphi_-$ corresponding to $x_{\text{eff}} = 0.144$, the Kerr-free point appears at $\varphi_+/2\pi = 0.07$ while, in Fig. 3(b), for $\varphi_-$ corresponding to $x_{\text{eff}} = 0.102$, the Kerr-free point appears at $\varphi_+/2\pi = 0.123$. This is in accordance with the fact that, for a SNAIL, the flux value at which the Kerr-free point is located depends on the value of $\varphi_-$\textsuperscript{12}. From additional Stark shift measurements of the same type in Figs. 3(a) and 3(b), we extract the Kerr coefficient as a function of $\varphi_-$ and $\varphi_+$, shown in Fig. 3(c). In this figure, it is possible to identify a Kerr-free line (KFL), which marks the boundary between positive (blue) and negative (red) Kerr, and it corresponds to a continuous region of the $\varphi_+$ plane with suppressed $K$. These data demonstrate that it is indeed possible to keep $K = 0$ for different combinations of bias phases, corresponding to different combinations of potential energy expansion coefficients $c_4$. In Fig. 3(d), we plot the Kerr constant predicted by theory based on the model presented in Ref. 3. The model is evaluated in the same range of $\varphi_-$ as in Fig. 3(c) and for the same set of fit parameters as used for the theory plot of the resonance frequency in Fig. 2(b). The theoretically predicted KFL deviates from the measured one in Fig. 3(c). The formula used in the theoretical evaluation of the Kerr...
This is in accordance with our theoretical analysis, which predicts 20 dB gain over the whole 1.7 GHz range in $x$-measure the resulting gain curve while varying probe signal frequency. The measured data, shown in Fig. 3(c), over which the device can operate when flux biased along the KFL in $\text{KFL}_0$. (d) Theory plot of Kerr constant. A Kerr-free line is predicted by theory, but it appears distorted with respect to the measured one.

assumes that the G-SNAILs are all identical, and in each G-SNAIL, the central array of three JTJs is made with identical elements. However, SEM inspection showed a 5% variation of $x$ along the array of G-SNAILs. Moreover, in each G-SNAIL, the array of three nominally identical JTJs was not uniform with the central JTJ having about 10% bigger area than the other two. These imperfections could be responsible for the mismatch between measured and simulated Kerr.

We can now evaluate the span of resonance frequencies $\omega_{\text{KFL}}$ over which the device can operate when flux biased along the KFL in Fig. 3(c). We perform 1-tone spectroscopy measurements for many combinations of $\varphi_6$ selected along the KFL and extract the correspondent resonance frequencies. The measured data, shown in Fig. 4(a), demonstrate that our device can operate with suppressed Kerr over a continuous range of frequencies of about 1.7 GHz.

Finally, to prove that our device is capable of three-wave mixing when flux biased along the KFL, we operate it as a parametric amplifier over the whole range of Kerr-free resonance frequencies in Fig. 4(a). For each value of $\omega_{\text{KFL}}$, we apply a pump at a frequency $2\omega_{\text{KFL}}$ and measure the resulting gain curve while varying probe signal frequency $\omega$. Gain data, presented in Fig. 4(b), show that it is possible to achieve 20 dB gain over the whole 1.7 GHz range in Fig. 4(a). This demonstrates that for all the combinations of flux biases $\varphi_6$ belonging to the KFL in Fig. 3(c), the expansion coefficient $c_3$ of potential energy (2) can be kept large enough to ensure three-wave mixing operations. This is in accordance with our theoretical analysis, which predicts $c_3$ variations across the experimentally measured KFL in Fig. 3(c) of less than a factor of 2 (not shown).

We want to clarify that the KFL in Fig. 3(c) does not exactly correspond to the region where we expect our device to have maximized dynamic range when operated as a parametric amplifier. In fact, the presence of a strong pump dresses the Kerr constant and shifts the positions of Kerr-free points from what predicted by Stark shift experiments. Nonetheless, with an additional tuning of $\varphi_6$ and an appropriate detuning of the pump frequency, our device should be capable of delivering 20 dB parametric amplification with a maximized dynamic range over a continuum of operating frequencies. This feature is under investigation in an optimized device whose flux-lines embed low-pass filters to limit the amount of internal losses, which were appreciable in our device. Such losses are indeed detrimental for a correct characterization of the dynamic range, which can result overestimated by a variable amount depending on the flux-bias condition.

In summary in this Letter, we presented an experimental demonstration of the advantages that a doubly flux biased G-SNAIL can provide in terms of potential energy engineering. In particular, it was shown that, when employed as elementary blocks of a parametric amplifier, G-SNAILs provide enough tunability to the potential energy expansion coefficients $c_2$, $c_3$, and $c_4$ to suppress the Kerr effect over a continuous region of the $\varphi_6$ plane, namely, a Kerr-free line. Moreover, when the flux biased along a KFL, our device was capable of three-wave mixing 20 dB amplification over a range of resonance frequencies of about 1.7 GHz.

From our perspective, G-SNAILs are promising candidates as elementary blocks of a high performance three-wave mixing traveling wave parametric amplifier (TWPA), a device that requires to simultaneously satisfy impedance- and phase-matching conditions. As the former is controlled by the linear response of the employed device, while the latter is strongly affected by Kerr, we believe that the G-SNAIL could provide enough tunability to a TWPA in order to satisfy...
both requirements while being capable of three-wave mixing amplification, as suggested by the experimental data presented in this paper. Overall, the flexibility of G-SNAILs can be beneficial for all the applications based on superconducting circuits, where it is required to properly balance the efficiency of two parametric processes to maximize performance.\(^\text{6,12}\)
