The Body Adiposity Index (Hip Circumference ÷ Height\(^{1.5}\)) Is Not a More Accurate Measure of Adiposity Than Is BMI, Waist Circumference, or Hip Circumference

David S. Freedman\(^1\), John C. Thornton\(^2\), F. Xavier Pi-Sunyer\(^2\), Steven B. Heymsfield\(^3\), Jack Wang\(^2\), Richard N. Pierson Jr\(^2\), Heidi M. Blanck\(^1\) and Dympna Gallagher\(^4\)

Based on cross-sectional analyses, it was suggested that hip circumference divided by height\(^{1.5} - 18\) (the body adiposity index (BAI)), could directly estimate percent body fat without the need for further correction for sex or age. We compared the prediction of percent body fat, as assessed by dual-energy X-ray absorptiometry (PBF\(_{\text{DXA}}\)) by BAI, BMI, and circumference (waist and hip) measurements among 1,151 adults who had a total body scan by DXA and circumference measurements from 1993 through 2005. After accounting for sex, we found that PBF\(_{\text{DXA}}\) was related similarly to BAI, BMI, waist circumference, and hip circumference. In general, BAI underestimated PBF\(_{\text{DXA}}\) among men (2.5%) and overestimated PBF\(_{\text{DXA}}\) among women (4%), but the magnitudes of these biases varied with the level of body fatness. The addition of covariates and quadratic terms for the body size measures in regression models substantially improved the prediction of PBF\(_{\text{DXA}}\), but none of the models based on BAI could more accurately predict PBF\(_{\text{DXA}}\) than could those based on BMI or circumferences. We conclude that the use of BAI as an indicator of adiposity is likely to produce biased estimates of percent body fat, with the errors varying by sex and level of body fatness. Although regression models that account for the nonlinear association, as well as the influence of sex, age, and race, can yield more accurate estimates of PBF\(_{\text{DXA}}\), estimates based on BAI are not more accurate than those based on BMI, waist circumference, or hip circumference.

Obesity (2012) 20, 2438–2444. doi:10.1038/oby.2012.81

INTRODUCTION

Although the limitations of the BMI are well known (1,2), this index remains widely used as a simple indicator of adiposity, and adults with a BMI of 30 kg/m\(^2\) or more are considered to be obese. An alternative index based on hip circumference and height, termed the body adiposity index (BAI), was recently proposed (3):

\[
\text{BAI} = \frac{\text{Hip circumference}}{\text{Height (m)}^{1.5}} - 18
\]

This ratio was derived from the cross-sectional associations of hip circumference \((r = 0.60)\) and height \((r = -0.52)\) with percent body fat calculated from dual-energy X-ray absorptiometry (PBF\(_{\text{DXA}}\)) among 1,733 Mexican-American adults (61%, women). The power of 1.5 was chosen to maximize the correlation between hip ÷ height and PBF\(_{\text{DXA}}\) \((r = 0.79)\) and 18 was the estimated intercept of a linear regression model predicting PBF\(_{\text{DXA}}\). It was concluded that BAI could directly estimate body fatness without the need for further adjustment for characteristics such as sex and age (3). Data presented in a recent letter (4), however, suggests that following stratification by race and sex, BMI may be as strongly correlated with PBF\(_{\text{DXA}}\) as is BAI.

The use of hip circumference in the numerator of an adiposity index is also surprising. Persons with larger hip circumferences, relative to BMI, are at lower risk for coronary heart disease and total mortality (5). In addition, the protective effect of a large hip circumference, as compared with waist circumference, is also suggested by its use in the denominator of the waist-to-hip ratio (6,7). This simple index of fat distribution has been associated with the development of type 2 diabetes (8–10) and coronary heart disease (7,11), but it is not certain if its effects are independent of BMI (12).
The purpose of the present study is to compare the relation of PBFDXA to various body size measures: BAI, BMI, hip circumference, and waist circumference. We also examine whether the prediction of PBFDXA by BAI is more accurate than that achieved by other measures of body size. The analytic sample comprises 1,151 adults who participated in studies conducted at the Body Composition Unit of the New York Obesity Nutrition Research Center between 1993 and 2005.

METHODS AND PROCEDURES

Design and analytic sample

The present study is based on cross-sectional data from 1,151 healthy adults (ages, 18–110 years) who participated in one of 11 studies conducted at the Body Composition Unit of the New York Obesity Nutrition Research Center. Study participants were examined between 1993 and 2005 (mean, 1997). All studies obtained written informed consent and were approved by the Radiation Safety Committee and Institutional Review Board of St Luke’s-Roosevelt Hospital. Subjects were included in the current analysis if they were healthy and ambulatory, with no known health condition that would affect body composition, and had a total body DXA scan to determine percent body fat (PBFDXA) and a hip circumference measurement. The 1,151 subjects included in the current analyses were not missing data for any of the examined characteristics.

Examinations, anthropometry, and laboratory procedures

Race-ethnicity was based on self-reported data and included information on the race-ethnicity of parents and grandparents. Subjects in the present study were classified into five categories: white (37%), black (27%), Hispanic (25%), Asian (8%), and “other” (3%). About 75% of subjects categorized as Hispanic reported family origins in Puerto Rico or the Dominican Republic. Asians were largely of Japanese, Chinese, or Korean descent.

Height was measured to the nearest 0.1 cm with a wall-mounted stadiometer, and body weight to the nearest 0.1 kg using a balance beam scale with the subjects wearing a hospital gown. Waist and hip circumferences were measured using a heavy-duty inelastic plastic fiber tape measure placed directly on the skin at the level of the iliac crest (for waist) and at the maximum extension of the buttocks (for hip) (13). The intraclass correlations for repeated measurements in the body composition unit were >0.99 for both waist (14) and hip circumference. The BAI was calculated as (hip circumference (cm) ÷ height (m) 1.5) – 18 (3). BAI estimates of percent body fat in the present study ranged from 13 to 45% among men and from 16% to 60% among women.

DXA scans were performed using either a Lunar DPX (software versions 1.3 and 1.5) or Lunar DPX-L (software versions 3 and 4). Quality control for fat and fat-free mass measurement was assessed using soft tissue phantoms of water (coefficient of variation = 1.5 to 1.6%) and alcohol (coefficient of variation = 0.6 to 1.3%). PBFDXA was calculated by dividing the total fat value (kg) by the total body mass as measured by the scanner. As previously reported (15), the equation PBFDXA = –0.5532 + 0.9813 × PBFDXA was used to convert the DPX estimates to their comparable DPX-L values. DPX-L estimates of percent body fat are used throughout the article.

Both models have been validated for the measurement of fat mass, lean mass, and bone mineral content using the 4-compartment model as a reference (16–18).

Statistical analyses

Because it has been suggested that BAI is a better index of adiposity than BMI (3), the analyses focus on comparing the relation of PBFDXA to BAI and BMI. We also examine the relation of PBFDXA to waist and hip circumferences to determine if these characteristics are as strongly associated with body fatness as BAI. All analyses were performed using R (19).

Several comparisons examined differences in the magnitudes of the correlations with PBFDXA. For example, to determine whether PBFDXA was more strongly associated with levels of BAI than with BMI, we examined the difference between (i) the correlation of PBFDXA and BAI, and (ii) the correlation of PBFDXA and BMI. Because BMI and BAI are correlated, we assess the statistical significance of this difference using tests for correlated coefficients (20,21); the null hypothesis is that the two correlations with PBFDXA are identical. Similar tests were performed to assess whether the waist and hip circumferences were as strongly associated with PBFDXA as was BAI. Several results were confirmed using bootstrap resampling (22). To adjust for sex and age, we calculated the correlation coefficients using the residuals of linear models that regressed the various body size measures on sex and age. P < 0.01 was used to assess statistical significance.

To assess whether BAI could accurately estimate PBFDXA, we first plotted levels of both characteristics for each subject. Bland–Altman plots were then constructed by plotting the observed differences (BAI – PBFDXA) against the mean of the two characteristics (23). A smoothed lowess (24) curve was added to each plot to indicate the pattern of these differences.

We also compared the ability of various regression models of varying complexity, based on each body size measure, to predict PBFDXA. Age, sex, and race were considered as additional covariates in these models. We examined the R2, the residual standard error (root mean square error), and the median absolute difference between predicted and observed values of PBFDXA.

RESULTS

Descriptive characteristics of the sample are shown in Table 1. Mean ages were 45 years (men) and 48 years (women), and 15% of men and 36% of women were obese (BMI ≥30 kg/m2). As compared with women, men had substantially lower mean levels of PBFDXA (21%, men vs. 35%, women) and BAI (24, men vs. 33, women). The higher BAI s of women were attributable to greater body fat, as compared with men, whereas BMI was similar.

Table 1: Mean levels of various characteristics, by sex, among adults

| Men (n = 383) | Women (n = 768) |
|--------------|----------------|
| Age (years)  | 45 ± 19*       | 48 ± 19       |
| Weight (kg)  | 78 ± 14        | 71 ± 17       |
| Height (m)   | 1.73 ± 0.08    | 1.60 ± 0.07   |
| BMI (kg/m²)  | 25.8 ± 4.3     | 27.6 ± 6.4    |
| BMI ≥30 (kg/m²) | 15%           | 36%          |
| Waist circumference (cm) | 89 ± 12 | 84 ± 14 |
| Hip circumference (cm) | 97 ± 10 | 102 ± 14 |
| Body adiposity index | 24.4 ± 5.1 | 32.5 ± 7.4 |
| Percent body fat (DXA) (%) | 20.5 ± 8.4 % | 35.0 ± 9.8 % |
| Race – ethnicity |
| %White       | 30%           | 40%          |
| %Black       | 21%           | 30%          |
| %Hispanic    | 35%           | 20%          |
| %Asian       | 9%            | 8%           |
| %Other       | 6%            | 2%           |

PBFDXA, percent body fat calculated from dual-energy X-ray absorptiometry.

*Values are mean ± SD or percent. Calculated as (hip circumference (cm) ÷ height (m) 1.5) – 18.
to their larger hip circumferences (97 cm, men vs. 102 cm, women) and their lower heights. Overall, 37% of the subjects were white, 27% were black and 25% were Hispanic.

Interrelationships among the anthropometric characteristics are shown in Table 2. In analyses of men and women together \((n = 1,151)\), PBF\(_{D\text{XA}}\) was more strongly correlated with BAI \((r = 0.86)\) than with BMI \((r = 0.74)\), and both hip \((r = 0.76)\) and waist circumference \((r = 0.55)\); \(P < 0.01\) for each comparison. (The null hypothesis was that magnitude of the correlation between PBF\(_{D\text{XA}}\) and BAI was equal to the relation of PBF\(_{D\text{XA}}\) to each of the other three characteristics.) In addition, analysis of all 1,151 subjects indicated that PBF\(_{D\text{XA}}\) was almost as strongly associated with height \((r = -0.43)\) as with weight \((r = 0.47)\).

However, stratified analyses in Table 2 indicated that the stronger association between PBF\(_{D\text{XA}}\) and BAI was largely due to confounding by sex. Among men and women separately, there was little difference in the relation of PBF\(_{D\text{XA}}\) to levels of BAI, BMI or circumferences, with correlations ranging from \(r = 0.75\) (hip circumference) to \(r = 0.80\) (waist circumference) among men and from \(r = 0.81\) (waist circumference) to \(r = 0.85\) (BMI) among women. As assessed by a test for the equality of these correlation coefficients, the only association with PBF\(_{D\text{XA}}\) that significantly differed from that with BAI was the PBF\(_{D\text{XA}}\) vs. BMI association. Among women, PBF\(_{D\text{XA}}\) was more strongly associated with BMI than with BAI \((r = 0.85 \text{ vs. } r = 0.82)\); \(P < 0.01\) for difference. The magnitudes of the association between PBF\(_{D\text{XA}}\) and height were also substantially reduced in these stratified analyses.

Controlling for both sex and age (Table 3) indicated that adjusted levels of PBF\(_{D\text{XA}}\) were more strongly correlated with BMI than with BAI \((r = 0.80 \text{ vs. } 0.76\), \(P < 0.01\) for difference). The difference between the two correlation coefficients was most evident among women \((r = 0.78 \text{ (BAI)} \text{ and } r = 0.82 \text{ (BMI)})\), whereas there was little difference in the associations among men. Age stratified analyses indicated that BMI was at least as strongly associated with PBF\(_{D\text{XA}}\) as was BAI, with statistically significant differences \((r_{\text{BMI}} > r_{\text{BAI}})\) among 18–34-year-olds and those who were at least 60 years of age. PBF\(_{D\text{XA}}\) was also more strongly associated with BMI than with BAI among both whites and blacks. None of the comparisons in Table 3 indicated that PBF\(_{D\text{XA}}\) was more strongly associated with BAI that with BMI or the circumferences. In some groups (blacks, whites, and older persons) hip circumference was also a stronger correlate of PBF\(_{D\text{XA}}\) than was BAI.

Figure 1 shows levels of BAI and PBF\(_{D\text{XA}}\) for the 383 men and 768 women. If BAI provided an unbiased estimate of body fatness, the points would be scattered symmetrically around the line of identity. The overall standard deviation of the difference between BAI and PBF\(_{D\text{XA}}\) was 6.3%, but these differences varied by sex. Among men, the mean difference \((\text{BAI} – \text{PBF}_{D\text{XA}})\) was 3.9%, but among women, the mean difference was –2.4%. The bias in using BAI to estimate PBF\(_{D\text{XA}}\) also varied by the level of body fatness with the overestimation of percent body fat by BAI most evident at low levels of body fatness.

The agreement between BAI and PBF\(_{D\text{XA}}\) is further examined in Bland–Altman plots (Figure 2), in which the difference \((\text{BAI} – \text{PBF}_{D\text{XA}})\) vs. the mean is plotted for each person. Although BAI generally overestimated PBF\(_{D\text{XA}}\) among men, the overestimation was more than 10% among men with low levels of body fatness, but close to 0 among men with levels of body fatness above 25%. (The lines in Figure 2 are loess curves, showing smoothed estimates of the difference by levels of body fatness.) BAI also overestimated PBF\(_{D\text{XA}}\) among women at low levels of body fatness, but underestimated PBF\(_{D\text{XA}}\) (points below years = 0 in plot) at moderate to high levels. Overall, BAI overestimated PBF\(_{D\text{XA}}\) among 75% of men and underestimated PBF\(_{D\text{XA}}\) among 70% of women.

### Table 2. Intercorrelations among the anthropometric characteristics, by sexa

| Sex          | Percent Body fat | Body adiposity index | BMI     | Circumferences | Hip   | Waist | Weight | Height | Age  |
|--------------|------------------|----------------------|--------|---------------|-------|-------|--------|--------|------|
| Overall      |                  |                      |        |               | 0.74* | 0.55* | 0.47   | –0.43  | 0.31 |
| Percent body fat | 1                | 0.86                 | 0.83   | 0.76          | 0.84  | 0.63  | 0.48   | –0.55  | 0.35 |
| Body adiposity index | 0.86            | 1                    | 0.83   | 0.76          | 0.91  | 0.87  | 0.86   | –0.14  | 0.20 |
| BMI          |                  |                      |        |               | 0.91  | 0.87  | 0.86   | –0.14  | 0.20 |
| Men          |                  |                      |        |               | 0.75  | 0.80  | 0.59   | –0.19  | 0.31 |
| Percent body fat | 1              | 0.77                 | 0.79   | 0.91          | 0.81  | 0.78  | 0.46   | –0.47  | 0.34 |
| Body adiposity index | 0.77          | 1                    | 0.79   | 0.91          | 0.86  | 0.89  | 0.86   | –0.06  | 0.12 |
| BMI          |                  |                      |        |               | 0.83  | 0.81  | 0.78   | –0.07  | 0.34 |
| Women        |                  |                      |        |               | 0.88  | 0.85  | 0.73   | –0.33  | 0.37 |
| Percent body fat | 1              | 0.82                 | 0.90   | 0.88          | 0.83  | 0.81  | 0.78   | –0.07  | 0.34 |
| Body adiposity index | 0.82           | 1                    | 0.90   | 0.88          | 0.83  | 0.81  | 0.78   | –0.07  | 0.34 |
| BMI          | 0.85             | 0.90                 | 1      | 0.92          | 0.92  | 0.92  | 0.92   | –0.06  | 0.22 |

All correlation coefficients are statistically significant at the 0.001 level \((H_0: r = 0)\) with the exception of those between BMI and both height \((r = 0.06)\) and age \((r = 0.12)\) among men, and between height and both percent body fat \((r = 0.07)\) and BMI \((r = 0.06)\) among women. BAI, body adiposity index; PBF\(_{D\text{XA}}\), percent body fat calculated from dual-energy X-ray absorptiometry. \(P < 0.01\) for difference. \(P\) value assesses whether the correlation between PBF\(_{D\text{XA}}\) and BAI is equal to the correlation between PBF\(_{D\text{XA}}\) and BMI, hip circumference, or waist circumference. The null hypothesis is that the correlation between PBF\(_{D\text{XA}}\) and BAI is equal to the correlation of PBF\(_{D\text{XA}}\) with each of the other characteristics.
Table 4 examines the prediction accuracy of PBF\textsubscript{DXA} by the four body size measures (BAI, BMI, and the two circumferences) in various regression models. In models based on only a single linear term for each body size measure (model #1), BAI was the strongest predictor of PBF\textsubscript{DXA}, with a $R^2$ of 0.74. (The estimates for hip circumference ÷ height$^{1.5}$ in this model, however, were $-31$ (intercept) and 1.28 (slope), values that differ substantially from those reported ($-18$ and 1.0) by Bergman et al. (3).) Allowing for different intercepts for men and women (model #2) reduced the differences among the body size measures, with multiple $R^2$s ranging from 0.77 (waist circumference and BMI) to 0.79 (BMI). An examination of the residuals from model #2, however, indicated that the errors varied with the level of body fatness, and nonlinear terms were therefore included in the model #3, slightly increasing the multiple $R^2$s. Subsequent inclusion of age (model #4) and race-ethnicity (model #5) further increased the $R^2$ values, with the highest $R^2$s seen for BMI (0.84 to 0.85). Of the various models (#5), those based on either BMI or hip circumference were better ($p<0.01$) predictors of percent body fat than was the model containing BAI.
Our results indicate that BAI is a stronger correlate of PBF\textsubscript{DXA} than is BMI only in analyses that fail to control for sex or age. Stratification by sex eliminates this difference, with PBF\textsubscript{DXA} being related similarly ($r = 0.75$ to 0.80 among men and $r = 0.81$ to 0.85 among women) to BAI, BMI, waist circumference, and hip circumference. Further adjustment for age confirmed that BAI was not a stronger correlate of PBF\textsubscript{DXA} than were these other body size measures. Although differences in the magnitudes of the correlations with PBF\textsubscript{DXA} were relatively small, in several instances (e.g., women), the observed correlation with BMI was stronger ($p < 0.01$) than that with BAI.

Although it has been suggested (3) that BAI can provide an estimate of percent body fat without the need for further adjustment, our results indicate that these estimates will be systematically biased by sex and the level of fatness. On average, BAI overestimated PBF\textsubscript{DXA} by 4% among men and underestimated PBF\textsubscript{DXA} among women by 2.5%, biases that are fairly similar to the those reported among subjects in the Fels Longitudinal Study (25). Although BAI was found to underestimate PBF\textsubscript{DXA} by about 7% among 132 women (26), this may have been due to their high BMIs (mean, 35.0 kg/m\textsuperscript{2}). Because the bias associated with BIA varies substantially by the level of body fatness (Figure 2), it would be expected that sex differences across studies would vary somewhat depending upon study-specific levels of fatness. It should also be noted that bias in estimating percent body fat by BAI in the study of Bergman et al. (3) varied by the level of fatness, but this was not discussed.

The simplicity of BAI has also been emphasized, but it is uncertain whether it is easier to calculate percent body fat from (hip circumference (cm) ÷ height (m) \textsuperscript{1.5}) – 18 than estimating body fatness from regression models. Our results (model #2, Table 4), for example, indicate that subtracting 13.6 (men) or 1.5 (women) from 1.32 × BMI would more accurately predict PBF\textsubscript{DXA} than does BAI. However, if one desired to use hip circumference ± height\textsuperscript{1.5} to predict PBF\textsubscript{DXA}, our results indicate that the estimates for the best-fitting regression line are −31 (intercept) and 1.28 (slope), values that differ substantially from those reported (−18 and 1.0) by Bergman et al. (Bergman ‘11), but very similar to estimates in the Fels Study (−33 and 1.26) (25). However, the prediction of percent body fat from either BAI or BMI (based on only a linear term) should be interpreted cautiously as estimates are likely to vary systematically with the level of body fatness.

These findings extend previous studies of adults (27–29) that have showed that (i) BAI is less strongly associated with skin-fold thicknesses and risk factors (lipids, insulin, glucose, and blood pressure) than is BMI, and (ii) the hip circumference is as strongly correlated with levels of skin-folds and risk factors as BAI. The similarity of the associations with hip circumference and BAI in the present study likely result from weak relation of body fatness to height among adults that we and others (30–32) have observed. It has long been assumed that an optimal index of adult obesity would show little correlation with height (33,34).

As has been suggested by Schulze and Stefan (35), it is likely that the original derivation of BAI (3) was strongly confounded by sex. The potential for confounding is emphasized in our results, as well as in an analysis of 3,851 adults from Baton Rouge (4) that found that PBF\textsubscript{DXA} was more strongly correlated with BAI than with BMI only in an analysis that combined men and women together. The effects of confounding in the study by Bergman et al. (3) are also evident in the stronger relation of PBF\textsubscript{DXA} to height ($r = −0.52$) than to weight ($r = 0.23$). Although the inverse association between PBF\textsubscript{DXA} and height resulted in standardizing hip circumference for height (3), this association was based on an analyses that grouped men and women together. Because women are generally shorter than men and have more body fat, an analysis of the association between height and body fatness would greatly overstate the strength of the association. In the present study, for example, the unadjusted correlation between height and PBF\textsubscript{DXA} was $r = −0.43$ (Table 2), but associations were reduced to $|r| < 0.10$ in sex-specific analyses that adjusted for age. Similar associations have also been observed in NHANES 1999–2004 (D.S. Freedman, unpublished data), with height being inversely correlated with PBF\textsubscript{DXA} ($r = −0.50$) among all adults ($n = 12,957$).

### Table 4 Various models comparing the prediction of PBF\textsubscript{DXA} by BAI, BMI, Hip circumference, or waist circumference

| Model | Predictors of PBF\textsubscript{DXA} | $R^2$ | Residual standard error<sup>a</sup> | Median, absolute error |
|-------|-------------------------------------|------|--------------------------------------|-----------------------|
| 1     | Linear term                         | 0.74 | 6.0                                  | 4.0                   |
| 2     | Linear term + sex                   | 0.77 | 5.5                                  | 3.6                   |
| 3     | Linear and nonlinear terms + sex    | 0.80 | 5.2                                  | 3.4                   |
| 4     | Model #3 + age                      | 0.80 | 5.1                                  | 3.3                   |

<sup>a</sup>The overall standard deviation of PBF\textsubscript{DXA} was 11.6 and the standard deviation of the difference between BAI and PBF\textsubscript{DXA} was 6.3. <sup>b</sup>The estimated equations predicting PBF\textsubscript{DXA} BAI BMI Hip Waist BAI BMI Hip Waist BAI BMI Hip Waist

**DISCUSSION**

The simplicity of BAI has also been emphasized, but it is uncertain whether it is easier to calculate percent body fat from (hip circumference (cm) ÷ height (m) \textsuperscript{1.5}) – 18 than estimating body fatness from regression models. Our results (model #2, Table 4), for example, indicate that subtracting 13.6 (men) or 1.5 (women) from 1.32 × BMI would more accurately predict PBF\textsubscript{DXA} than does BAI. However, if one desired to use hip circumference ± height\textsuperscript{1.5} to predict PBF\textsubscript{DXA}, our results indicate that the estimates for the best-fitting regression line are −31 (intercept) and 1.28 (slope), values that differ substantially from those reported (−18 and 1.0) by Bergman et al. (Bergman ‘11), but very similar to estimates in the Fels Study (−33 and 1.26) (25). However, the prediction of percent body fat from either BAI or BMI (based on only a linear term) should be interpreted cautiously as estimates are likely to vary systematically with the level of body fatness.

These findings extend previous studies of adults (27–29) that have showed that (i) BAI is less strongly associated with skin-fold thicknesses and risk factors (lipids, insulin, glucose, and blood pressure) than is BMI, and (ii) the hip circumference is as strongly correlated with levels of skin-folds and risk factors as BAI. The similarity of the associations with hip circumference and BAI in the present study likely result from weak relation of body fatness to height among adults that we and others (30–32) have observed. It has long been assumed that an optimal index of adult obesity would show little correlation with height (33,34).

As has been suggested by Schulze and Stefan (35), it is likely that the original derivation of BAI (3) was strongly confounded by sex. The potential for confounding is emphasized in our results, as well as in an analysis of 3,851 adults from Baton Rouge (4) that found that PBF\textsubscript{DXA} was more strongly correlated with BAI than with BMI only in an analysis that combined men and women together. The effects of confounding in the study by Bergman et al. (3) are also evident in the stronger relation of PBF\textsubscript{DXA} to height ($r = −0.52$) than to weight ($r = 0.23$). Although the inverse association between PBF\textsubscript{DXA} and height resulted in standardizing hip circumference for height (3), this association was based on an analyses that grouped men and women together. Because women are generally shorter than men and have more body fat, an analysis of the association between height and body fatness would greatly overstate the strength of the association. In the present study, for example, the unadjusted correlation between height and PBF\textsubscript{DXA} was $r = −0.43$ (Table 2), but associations were reduced to $|r| < 0.10$ in sex-specific analyses that adjusted for age. Similar associations have also been observed in NHANES 1999–2004 (D.S. Freedman, unpublished data), with height being inversely correlated with PBF\textsubscript{DXA} ($r = −0.50$) among all adults ($n = 12,957$).
while sex-specific correlations are \( r = -0.02 \) (men) and \( r = -0.10 \) (women). Analyses of body fatness that do not control for sex should be interpreted very cautiously.

There are several potential limitations of the present study. Our sample is not representative of the general population, and levels of BMI and hip circumferences were lower than those in the study of Bergman et al. (3). Furthermore, although DXA estimates of body fatness are highly correlated with those from methods such as the 4-compartment model and neutron activation (36), there can be large differences for an individual subject. DXA estimates of percent body fat also can also vary by manufacturer and across models. Estimates of body fatness may also vary systematically, with DXA underestimating the body fatness of leaner persons and overestimating the body fatness of obese persons (37). Although the use of two different pencil-beam DXA systems in the present study likely resulted in additional errors, a previous study (38) found good agreement (CV = 4.4\%) in estimates of fat mass between the two systems. Although there can also be differences in the measurement of hip circumference, the maximum extension of the buttocks was measured in the present study and in the analysis of Bergman et al. (3).

In summary, we found that after accounting for the differences in body fatness between men and women, PBF\textsubscript{DXA} is not more strongly correlated with BAI than levels of BMI, waist circumference, or hip circumference. Although differences in the relation of these body size measures to PBF\textsubscript{DXA} were relatively small, in several instances, the adjusted associations with BMI or hip circumference were significantly (\( P < 0.01 \)) stronger than those with BAI. If the accurate measurement of weight (and calculation of BMI) is difficult, circumference measurements could be considered, but the use of BAI has no advantage over the use of either waist or hip circumference.
