ABSTRACT

Multi-wavelength observations/spectroscopy of exoplanetary atmospheres are the basis of the emerging exciting field of comparative exoplanetology. The HR 8799 planetary system is an ideal laboratory to study our current knowledge gap between massive field brown dwarfs and the cold 5 Gyr old solar system planets. The HR 8799 planets have so far been imaged at J- to L-band, with only upper limits available at M-band. We present here deep high-contrast Keck II adaptive optics M-band observations that show the imaging detection of three of the four currently known HR 8799 planets. Such detections were made possible due to the development of an innovative LOCI-based background subtraction scheme that is three times more efficient than a classical median background subtraction for Keck II AO data, representing a gain in telescope time of up to a factor of nine. These M-band detections extend the broadband photometric coverage out to \( \sim 5 \mu m \) and provide access to the strong CO fundamental absorption band at \( 4.3 \mu m \). The new M-band photometry shows that the HR 8799 planets are located near the L/T-type dwarf transition, similar to what was found by other studies. We also confirm that the best atmospheric fits are consistent with low surface gravity, dusty, and non-equilibrium CO/CH4 chemistry models.

1. INTRODUCTION

After more than a decade of searching, the direct exoplanet imaging quest was finally successful in 2008 with the discovery of three planetary systems (Marois et al. 2008b; Kalas et al. 2008; Lagrange et al. 2009). One key advantage of this technique is the detection of the planet’s thermal emission. Detailed multi-band photometry and spectroscopy can be acquired that can then be compared with atmospheric models to derive the planet’s physical characteristics and study the effect of dust and molecular chemistry. With its multiple coeval Jovian planets, the HR 8799 system is an ideal laboratory to study young planets with low temperature/surface gravity atmospheres and bridge the gap between massive field brown dwarfs and the cold solar system planets.

HR 8799 is a 30 Myr old (Marois et al. 2010b; Zuckerman et al. 2011) A5V star located 39.4 pc away (Leeuwen 2007) in the Pegasus constellation. It is classified as a \( \gamma \) Doradus and a \( \lambda \) Bootis star (Gray & Kaye 1999). It also shows an IR excess (Vega-like star) consistent with a debris disk composed of a warm dust disk (6–15 AU), a massive cold dust disk (90–300 AU), and a small dust particle halo extending up to a 1000 AU (Rhee et al. 2007; Su et al. 2009).

Photometry and some spectroscopy of the HR 8799 planets are available in several bands from 1 to 3.8 \( \mu m \) (Marois et al. 2008b, 2010b; Lafrenière et al. 2009; Metchev et al. 2009; Janson et al. 2010; Hinz et al. 2010; Currie et al. 2011; Barman et al. 2011). An initial characterization (Marois et al. 2008b, 2010b; Bowler et al. 2010; Currie et al. 2011; Barman et al. 2011) has been achieved using the available data and state-of-the-art atmospheric models developed for field brown dwarf analysis. It is clear that these planets are quite different than most field brown dwarfs, showing very dusty atmospheres while being cool (~1000 K) with no sign of methane molecular absorption. L- and M-band detections/upper limits suggest that this lack of methane is due to a CO/CH4 non-equilibrium chemistry (Saumon et al. 2003; Cushing et al. 2006; Leggett et al. 2007; Hinz et al. 2010; Bowler et al. 2010; Currie et al. 2011; Barman et al. 2011). Other teams have been able to fit the available photometry with patchy clouds and equilibrium chemistry atmospheres (Marois et al. 2008b; Currie et al. 2011). Accurate M-band photometry can help disentangle the various models, but it is hard on a ground-based telescope due to the bright thermal background mainly from the telescope and the adaptive optics system (Lloyd-Hart 2000). This background is particularly hard to remove at Keck, as it varies with time as the instrument image rotator (which is located very near focus) moves and as the AO deformable mirror modulates the rotator-induced background pattern as seen by the detector. As a result, conventional sky/background subtraction routines leave a spatially variable residual that limits final sensitivity.

In this Letter, we present the first M-band (4.670 \( \mu m \)) detections of three of the currently four known HR 8799 planets, the longest wavelength at which these planets have been imaged. The observations are discussed in Section 2. The data reduction along with the new very efficient LOCI-based (LOCI: locally optimized combination of images) background subtraction technique are presented in Section 3. Comparisons with field brown dwarfs and new atmospheric fits are shown in Section 5. Conclusions are summarized in Section 6.

2. OBSERVATIONS

The HR 8799 data were obtained on 2009 November 1 and 2 at the Keck II observatory using the adaptive optics system, the NIRC2 near-infrared narrow-field camera (McLean...
& Sprayberry 2003), and the $M$-band filter ($\lambda_0 = 4.670 \mu m$ and $\Delta \lambda = 0.241 \mu m$). No coronagraph was used for these observations. For these two nights, 140 unsaturated images (58 for November 1 and 82 for November 2) were acquired, each image consisting of 200 co-adds of 0.3 s, for a total on-source integration time of 140 minutes. The data were taken in angular image consisting of 200 co-adds of 0.3 s, for a total on-source for November 1 and 82 for November 2) were acquired, each observations. For these two nights, 140 unsaturated images (58

\[ \chi_p^2(\alpha_p^{1 \leq i \leq N}) = \sum_{i=1}^{N} \sum_{j=1}^{M} [\alpha_p^j I_i(x_j) - I_p(x_j)]^2 D(x_j), \]

where $M$ is the total number of images in the sequence, $N$ is the total number of images in the sequence, $x_j$ is the $j$th pixel, $I_i$ is the $i$th image of the sequence, and $\alpha_p^j$ the coefficients to be determined. The inner radius of area $D$ is chosen to avoid the bright star speckle noise that can bias the background minimization algorithm, while its outer radius is chosen to avoid the dithered star images. In our case, the inner and outer radii are 3 and 30 $\lambda/D$ corresponding to 24 to 240 pixels. We have then imposed $\alpha_p^j = 0$ if the star is at a similar location in $I_i$ as in $I_p$. The LOCI algorithm then finds the optimal $\alpha_p^{best}$ (Lafrenière et al. 2007; Marois et al. 2010a) that minimizes the $\chi_p^2$. The optimized background image $B_p$ at each pixel for $I_p$ (not only in $D$) is then

\[ B_p = \sum_{i=1}^{N} \alpha_p^{best} I_i. \]

The generated reference background image $B_p$ is finally subtracted from $I_p$. As $\alpha_p^{best} = 0$ for the images where the star is registered at the same location in $I_i$ as in $I_p$, $B_p$ does not contain any flux from a possible companion. Moreover, if a companion exists in $I_p$, its impact on the $\alpha_p^{best}$ LOCI coefficients is negligible since the companion flux is much smaller than the thermal background and $D$ is large compared to the companion point-spread function (PSF).

Once the background is subtracted, we sub-pixel register each image using an iterative cross-correlation Gaussian fit to the PSF core (images are unsaturated).

### 3.2. Median Speckle Subtraction

The speckle subtraction is performed following a basic ADI data reduction as described in Marois et al. (2006). For each data cube, an initial reference PSF is assembled by taking the median of all images and is then subtracted. We then rotate the images to put north up and median combine them. We apply an unsharp mask to the resulting image (median in a $4 \times 4 \lambda/D$
box) to remove the low spatial frequency noise and convolve it by a $0.5\lambda/D$ width Gaussian to average the high-frequency pixel-to-pixel noise. We finally average the November 1 and 2 images (Figure 2).

Without the LOCI background subtraction, none of the planets would have been detected (right panel, signal-to-noise ratio $(S/N)$ for d is less than 2). With the LOCI background subtraction, HR 8799b, c, and d are detected (left panel, 3–8 $S/N$). Planet e non-detection is probably due to both sequences not being acquired through transit, thus limiting the amount of speckle noise being removed at small separations from the median subtraction. We tried to apply a more advanced LOCI algorithm (Lafrenière et al. 2007; Marois et al. 2008a, 2010a) to improve the speckle reduction, but as the FOV rotation ranges were small for both nights, no contrast gain was achieved.

4. DATA ANALYSIS

Planet fluxes and positions were obtained by subtracting the planets prior to the speckle reduction using the stellar unsaturated PSF as the template. We also tried subtracting the companions prior to the LOCI-background algorithm and we have confirmed that no bias is introduced by this technique (final flux variations smaller than 0.07%). The subtraction was iterated by moving the planet template and changing its intensity until a minimal noise residual at the planet’s location was achieved (inside a $1.5\lambda/D$ radius area; Table 1 for the resulting magnitudes). Photometric error bars were calculated in $\lambda/D$ width annulus. As expected from other wavelengths (Marois et al. 2008b), HR 8799b flux is roughly a third of that of planets c and d. The planet’s positions are included in Table 1. The low $S/N$s and the large $M$-band PSF core result in large astrometric errors. A future astrometric HR 8799 paper using shorter wavelength astrometry is in preparation.

Contrast plots (central panel of Figure 2) were obtained by calculating the noise in an annulus having a $\lambda/D$ width normalized by the stellar PSF flux (after performing the same unsharp mask and convolution of a $0.5\lambda/D$ Gaussian). The contrast plots were then normalized at each separation by the estimated point source throughput using simulated ADI median process planets. Figure 2 shows that the LOCI background subtraction (black full line) is up to $\sim 3$ times better than a classical background median subtraction (red dotted line). If a classical background subtraction routine is used, an integration time of up to nine times longer is required to reach the same LOCI background subtraction contrast. This new highly efficient LOCI-based background subtraction routine can be used on any data where the background is non-negligible and evolving with time.

5. DISCUSSIONS

It has been shown that the HR 8799 planets are an L-type extension toward lower effective temperatures and lower surface gravities (Marois et al. 2008b; Bowler et al. 2010; Currie et al. 2011; Barman et al. 2011). The planets have also been found to be dusty with evidence of non-equilibrium CO/CH$_4$ chemistry. If the HR 8799 planets are plotted in $K’$ versus $L’$ or $M’$ diagram (Figure 3) against field brown dwarfs and lower mass stars (Leggett et al. 2007), it is found that the HR 8799 planets are located near the L/T-type dwarf transition. The $M$-band photometry is thus consistent with what was found previously by

![Figure 2](image-url)
Figure 3. $K$–$L$ vs. $L$–$M$ diagram for field brown dwarfs, lower mass stars, and the HR 8799 planets. The planets are located near the end of the L-type sequence, close to the T-type transition.

(A color version of this figure is available in the online journal.)

Figure 4. Comparison between the best solar-abundance model (red squares) and the broadband photometry (black cross) for HR 8799b (top), c (middle), and d (bottom). For planet b, the photometry from the 10 times more metal-rich case described in Barman et al. (2011) is plotted in green triangles. The photometric measurements other than for the $M$-band are from Marois et al. (2008b, 2010b) and Currie et al. (2011). We also show Currie et al. (2011) upper limits for the $M$-band photometry as a dotted line.

(A color version of this figure is available in the online journal.)

other studies. From the field brown dwarf best-fit parameters of Figures 4–6 of Leggett et al. (2007), we also find that the planet $L$- and $M$-band colors are consistent with dusty atmospheres with vertical mixing. Barman et al. (2011) found a similar result for HR 8799b while considering lower surface gravities.

If we compare our estimated $M$-band flux to Currie et al. (2011) equilibrium chemistry model predictions, we find that all their best-patchy-cloud atmospheric fits are rejected to $\sim 3\sigma$ for HR 8799b. For planets c and d, Currie et al. (2011) use equilibrium chemical models and focus on clouds to interpret the available photometry. The earlier work of Hinz et al. (2010) did compare different chemical models to their $M$-band upper limits for all three planets, but did not include near-IR photometry. Our new photometry is consistent with some models proposed by the two teams and will help in constraining their fits.

In this Letter, we compare cloudy and non-equilibrium model fits for all of the photometry for the three planets. Such comparison has only been done for planet b so far (Bowler et al. 2010; Barman et al. 2011). Using the same solar-abundance model atmosphere grids and procedures described in Barman et al. (2011), new gravities and effective temperatures are found (Figure 4). For planet b, we find similar model atmosphere parameters as in Barman et al. (2011), but with a slightly higher gravity—$\log(g) = 4$ rather than 3.5. This solar-abundance model has $T_{\text{eff}} = 1100$ K and, thus, requires a very small...
nearly a factor of two smaller than predicted by traditional hot-radius (Baraffe et al. 2003). For planets c and d, we find temperatures and gravities that are fairly close to the expected values from evolution models (Marois et al. 2008b). Barman et al. (2011) argue that increasing the metallicity to 10 times solar could bring the $T_{\text{eff}}/\log(g)$ derived from atmosphere and evolution models for planet b into better agreement. The photometry from this metal-rich, evolution-consistent, model is also shown in Figure 4. This model, however, predicts an $M$-band flux that is $3.5\sigma$ brighter than observed (while all other bands agree to $2\sigma$ or better). This may indicate an even higher overall metallicity and/or that a non-solar C-to-O ratio is required. A broader exploration of the possible metal abundances for all four planets will be left to a future paper.

6. CONCLUSIONS

In this Letter, we have estimated for the first time the $M$-band fluxes of three of the currently four known HR 8799 planets. These detections were made possible due to the use of an innovative LOCI-based background subtraction routine that has allowed for a factor of three gain in contrast (factor of nine in integration time) compared to a classical background subtraction using a median. This new background subtraction routine can be used to subtract the background noise in any infrared data.

We have detected HR 8799b, c, and d at $M$-band from 3 to 8$\sigma$. From a $K' - L'$ and $L' - M'$ color diagram, we confirm that the three planets are located near the end of the L-type sequence, close to the L- and T-dwarf transition region. We then derived new atmosphere model fits for the three planets. For planets c and d, temperatures and surface gravities are close to the expected values from evolutionary models. For planet b, the solar-abundance model fits well the broadband photometry from 1 to 5$\mu$m but it requires a very small planetary radius to match the bolometric luminosity and is thus in contradiction with the planet evolution models. The metal-rich evolution-consistent model overpredicts the $M$-band flux, which may indicate an even higher overall metallicity and/or a non-solar C-to-O ratio. Higher S/N images will help disentangle the different physical and chemical parameters.

The authors thank S. Leggett for kindly providing the Figure 3 field brown dwarf data. Portions of this work were performed under the auspices of the U.S. Department of Energy by Lawrence Livermore National Laboratory under Contract DE-AC52-07NA27344. The data presented herein were obtained at the W. M. Keck Observatory, which is operated as a scientific partnership among the California Institute of Technology, the University of California, and the National Aeronautics and Space Administration. The Observatory was made possible by the generous financial support of the W. M. Keck Foundation. The authors wish to recognize and acknowledge the very significant cultural role and reverence that the summit of Mauna Kea has always had within the indigenous Hawaiian community. We are most fortunate to have the opportunity to conduct observations from this mountain.
