Abstract

\textbf{Objectives:} Diabetic foot ulcers (DFUs) often lead to hospital admissions, amputations and deaths; however, there is no up-to-date information on microbial isolates from DFUs and no mention of utilization of molecular techniques in Sub-Saharan Africa. We conducted a cross-sectional study among 83 adult patients at a tertiary hospital in Kenya over 12 months. The study aimed to isolate, identify bacteria, their antibiotic susceptibility patterns in active DFUs, and to compare standard microbiological methods versus a real-time PCR commercial kit in the detection of \textit{Staphylococcus aureus} DNA and methicillin-resistant \textit{S. aureus} (MRSA) DNA.

\textbf{Results:} Eighty swabs (94\%) were culture-positive; 29\% were Gram-positive and 65\% were Gram-negative. The main organisms isolated were \textit{S. aureus} (16\%), \textit{Escherichia coli} (15\%), \textit{Proteus mirabilis} (11\%), \textit{Klebsiella pneumoniae} (7\%) and \textit{Pseudomonas aeruginosa} (7\%). The bacterial isolates showed resistance to commonly used antibiotics such as ampicillin, amoxicillin, cefepime, ceftazidime, cefuroxime, clindamycin, erythromycin, piperacillin–tazobactam, tetracycline and trimethoprim–sulphamethoxazole (TMP-SMX). Thirty-one percent of the \textit{S. aureus} isolated and 40\% of the Gram-negatives were multi-drug resistant organisms (MDROs). There was a high prevalence of nosocomial bacteria. MRSA were not identified using culture methods but were identified using PCR. PCR was more sensitive but less specific than culture-based methods to identify \textit{S. aureus}.

\textbf{Keywords:} Diabetic foot ulcers, Kenya, Multi-drug resistant organisms, Methicillin-resistant \textit{S. aureus}, Polymerase chain reaction

Introduction

It is estimated that 10–15\% of diabetic patients will develop diabetic foot ulcers (DFUs) at some point in their life [1, 2]. In Africa, the overall prevalence of DFUs was found to be 13\% in a recent meta-analysis [3]. At presentation, about half of DFUs are clinically infected [4]. \textit{Staphylococcus aureus} and beta-haemolytic \textit{Streptococci} are the most common causes of skin infections [5–11]. In resource-poor countries however, Gram-negatives like \textit{Pseudomonas aeruginosa} are more prevalent [6, 10]. In Kenya, \textit{S. aureus} and \textit{Escherichia coli} were found to be the most common organisms in DFIs [12]. More recently, 73.2\% of DFUs were infected while 26.8\% were culture-negative [13]. Fungal infections may also cause DFIs [14].

Antimicrobial resistance (AMR) is an emerging problem globally. Methicillin-resistant \textit{S. aureus} (MRSA) was first observed in the early 1960s and has been associated with increased hospital stay, healthcare costs and mortality [15]. MRSA represented 4.7\% of \textit{S. aureus} isolated in a study in Morocco [16]. In Brazil, 33\% cases of MRSA (cefoxitin-resistant) were vancomycin-resistant [17]. Multi-drug resistant organisms (MDROs) are bacteria that are resistant to more than one or more classes of antibiotics. In Tanzania, antibiotic susceptibility tests
of Clinical Research, University of Nairobi). Fifty-one samples were randomly selected from the 83 recruited patients and dissolved in 200 µL to 500 µL of Dulbecco’s phosphate buffered solution (Sigma®-Aldrich, Steinheim, Germany). Automated DNA extraction was performed using QIAster® (Qiagen®, Hilden, Germany) according to manufacturer’s instructions. PCR-amplification and real-time hybridization were conducted using the MRSA Quant Real-TM kit (Sacace™ Biotechnologies, Como, Italy). Amplification was set up in a 1.0 µL PCR tubes containing 15 µL of PCR Master Mix (PCR mix-1 FRT MRSA, PCR-mix-2 FRT, TaqF polymerase, and Internal Control). The reaction tubes were subjected to Thermal cycling reactions on a Rotor-Gene Q machine (Qiagen, Hilden, Germany) comprising of 15 min at 95 °C followed by 5 cycles of 15 s at 95 °C, 30 s at 60 °C, and 15 s at 72 °C, and finally 40 cycles of 15 s at 95 °C, 30 s at 55 °C and 15 s at 72 °C for measuring fluorescent signal.

Quality control
Positive controls for microbiological tests were recently collected (<7 days) positive specimens of bacteria from human samples that were stored at room temperature in cotton swabs in a safety cabinet. For the RT-PCR tests, quality control was assured by running 4 additional samples alongside the 51 specimen: Positive control, Negative control, DNA Quality Standard (QS) 1 MRSA and DNA QS2 MRSA.

Statistical analyses
Microsoft Excel was used for data entry and data analysis. Data was represented as frequencies, percentages, tables and charts. Comparison of microbiological and RT-PCR was based on absolute numbers, sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV). Both culture and real-time PCR were considered as the gold standard.

Results
Bacterial isolates and antimicrobial sensitivity tests
The most predominant growth on the culture plate per specimen was isolated. Out of 85 culture and susceptibility tests performed from 83 patients, 78 swabs had monomicrobial growth, 1 had poly-microbial growth (2 isolates) and 5 had no growth. Most organisms (64.71%, n = 55) were Gram-negative and (29.41%, n = 25) organisms were Gram-positive. The most common organisms isolated were S. aureus (16.47%, n = 14), E. coli (15.29%, n = 13), Proteus mirabilis (10.59%, n = 9), Klebsiella pneumoniae (7.06%, n = 6) and P. aeruginosa (7.06%, n = 6) (see Additional file 1: Figure S1). Some of the other rare bacteria isolated from patients included Staphylococcus lentus, Staphylococcus simulans, Staphylococcus xylosus,
Acinetobacter baumannii, Burkholderia cepacia, Kocuria kristinae, Leuconostoc mesenteroides, Pantoea agglomerans, Providencia stuartii and Raoultella ornithinolytica.

Staphylococcus aureus was highly resistant to benzylpenicillin and trimethoprim–sulphamethoxazole (TMPSMX) but sensitive to cefoxitin, oxacillin, nitrofurantoin, levofloxacin, linezolid, and vancomycin. There was no MRSA identified using microbiology tests. Isolates of S. epidermidis, S. intermedius and S. simulans were either 100% resistant, 50% resistant or 100% sensitive to the antibiotics tested (Additional file 2: Table S1). E. coli was highly resistant to ampicillin, aztreonam, cefuroxime and TMPSMX but sensitive to amikacin and nitrofurantoin (refer to Additional file 2: Table S2). P. mirabilis showed a similar resistance to ampicillin but sensitivity to amikacin. P. aeruginosa was sensitive to ampicillin, amoxicillin–clavulanic acid, aztreonam, cefazidime, ciprofloxacin, nitrofurantoin and TMPSMX. S. fonticola species showed resistance to ampicillin, amoxicillin, cefazolin, cefepime, ceftazidime, piperacillin-tazobactam and TMPSMX. About a third (30.77%, n = 4) of the S. aureus were MDROs while 40.38% (n = 21) Gram-negative bacilli were MDROs (Fig. 1).

**Culture-versus-molecular tests**

Molecular tests were performed on 51 out of the total 85 samples tested (Fig. 2). The RT-PCR results of the 51 samples were compared with the respective culture results for the detection of S. aureus and MRSA. For the Gram-positive pathogens, 11 were culture-positive for S. aureus while 7 yielded other Staphylococcus sp. RT-PCR for S. aureus was positive for 9 out of the 11 culture-positive results (see Additional file 2: Table S3). Five samples positive for S. aureus but negative for MRSA on culture-based methods were positive for MRSA on RT-PCR. Two samples positive for other Staphylococcus sp. and negative for S. aureus on culture were positive for MRSA on RT-PCR. One sample with other Staphylococcus sp. suspected to be skin contaminants based on microbiological tests underwent RT-PCR. The sample was negative for S. aureus on culture tests but positive for S. aureus and MRSA DNA on RT-PCR.

![Fig. 1](image-url)
One sample without any growth was subjected to RT-PCR. The sample was positive for *S. aureus* DNA but not MRSA DNA. Four (12.5%) samples that had Gram-negative bacteria based on culture tests were also positive for *S. aureus* on RT-PCR while 6 (18.8%) samples from these batch were positive for MRSA DNA (Additional file 2: Table S4). Of importance is that MRSA were not identified using culture methods but were identified using PCR. There was amplification for MRSA in one sample that was culture positive for *S. aureus* but negative during RT-PCR for this pathogen (Additional file 2: Table S3). Atypical amplification for MRSA occurred in four samples that were both culture and RT-PCR negative for *S. aureus* (Additional file 2: Table S4).

Further comparison was then made by statistical analyses. Firstly, culture methods were considered the assay and RT-PCR as the reference. The sensitivity of the

---

**Table 1** Comparison of RT-PCR and culture-based methods of *S. aureus* and MRSA in DFUs

| Species | Reference | Assay   | Sensitivity (%) | Specificity (%) | PPV (%) | NPV (%) |
|---------|-----------|---------|-----------------|-----------------|---------|---------|
| *S. aureus* | Culture | RT-PCR | 90.9            | 82.5            | 58.8    | 97      |
|          | RT-PCR   | Culture| 58.8            | 97              | 90.9    | 66.7    |
| MRSA    | Culture  | RT-PCR | 72.7            | 100             | 100     | 72.7    |

In this Table, both culture-methods and RT-PCR were used as gold standards. In the column heading, the gold standard is the “Reference” while the method being tested, the “Assay.”
VITEK® 2 machine to detect *S. aureus* was 90.9% while the specificity was 82.5% (Table 1 and Additional file 2: Table S5). The PPV was 58.8% while the NPV was 97.0%. The sensitivity and PPV of the culture tests to detect MRSA could not be calculated due to missing culture-positive results (Additional file 2: Table S5). However, its specificity was 72.7% and NPV was 100%. In the second case, the RT-PCR was considered the assay and culture tests as the reference. The sensitivity, specificity, PPV and NPV of the RT-PCR to detect *S. aureus* were 58.8%, 97.0%, 90.9% and 66.7% respectively (Table 1). For detection of MRSA, the specificity for the RT-PCR was 100% while the NPV was 72.7%.

**Discussion**

DFU is a chronic issue that contributes significantly to morbidity and mortality. In this study, over 90% of the DFUs were infected. This was higher than in earlier studies in Kenya, Tanzania, and Libya where approximately 70% of DFUs had positive cultures [13, 18, 20]. *S. aureus* was the most predominant single species isolated in DFUs as reported in other studies [2, 6–10, 12, 17, 18, 20]. In this current study, Gram-negative bacteria were more predominant than Gram-positive organisms similar to studies in Morocco and Brazil [16, 17]. Similar to previous studies, *E. coli* and *P. aeruginosa* were common in this study [6, 10, 12, 17, 20].

In this study, there was high AMR among the Gram-negative organisms compared to the Gram-positive bacteria. In fact, MDROs mainly consisted of Gram-negative bacteria. *S. aureus* was sensitive to most antibiotics including vancomycin whereas no MRSA was identified by culture methods (cefoxitin screen). From previous studies, MRSA is predominant in DFUs and shows limited AMR [21, 22]. In Brazil, 22% of DFUs had MRSA following cefoxitin screen, and 33% of these were also resistant to vancomycin [17]. *S. aureus* and *E. coli* isolated from DFUs were classified as MDROs in this earlier study. From previous studies, antibiotics that used to work before are now showing increasing resistance [12, 18].

Biofilms, present in chronic wounds, are a defensive mechanism for bacteria against the effects of antibiotics and can explain the rise in AMR [10, 11]. Unjustified use of antibiotics is another cause of AMR, misuse of health resources and a burden to patients and their families [6, 23, 24]. From this present study, amikacin is effective against most Gram-negative bacteria. The high AMR to ampicillin should warrant care during empirical treatment of DFUs in this setting [25]. Further, although some *E. coli* isolates were resistant to meropenem (a third-line antibiotic); all were sensitive to nitrofurantoin (a first-line antibiotic). There is therefore need to use antibiotics judiciously and be guided by routine culture and susceptibility tests.

However, more accurate tests should be explored since culture-based methods have been reported to have a high number of false-negatives [8]. In the present study, molecular tests were more sensitive but less specific than culture-based methods. PCR revealed pathogens that had not been recognized by culture-methods such as MRSA species. Previous research reveals a higher specificity for culture tests when compared to RT-PCR as a reference while a lower sensitivity, a slightly higher PPV and a higher NPV [8]. Similar to this earlier study, RT-PCR revealed more *S. aureus* than identified through culture-methods [8]. PCR is therefore an effective way of species identification in patients with DFUs.

**Limitations**

- Due to limited funding, only the most predominant organism was isolated from the samples. Further, anaerobic bacteria were also not identified.
- PCR technology may amplify dormant or dead bacteria in a sample.
- The study fails to explain the atypical amplification why RT-PCR is positive for MRSA but negative for *S. aureus*. Contamination or cross-reactivity is not a possibility since the RT-PCR kit should detect both *S. aureus* DNA and meca gene specific for MRSA.

Acknowledgements

We would like to acknowledge all the patients and their relatives without whom this study would not have been possible. We are most grateful to the nursing staff in the Department of Medicine and the Diabetes and Endocrinology Outpatient Clinic at Kenyatta National Hospital for their support. Our appreciation also goes to the laboratory staff at KNH Microbiology Laboratory and Bioceq Kenya Laboratory for running the tests.

Competing interests

The authors declare that they have no competing interests.

Availability of data and materials

All data generated or analysed during this study is included in this published article and supplementary information files. Additional datasets are publicly available on the University of Nairobi Library Research Archive Website (http://erepository.uonbi.ac.ke/8080/xmlui/handle/11295/105662) as part of the Master’s Thesis of the corresponding author in Tropical and Infectious Diseases, 2018.

Consent for publication

Not applicable.

Ethics approval and consent to participate

Ethical approval was sought from the KNH Ethics and Research Committee (Approval Number F769/10/2016, Website: http://erc.uonbi.ac.ke/) and KNH Department of Medicine (Registration Number: Med/101/2017). Patients were enrolled in the study only after written informed consent was taken.

Funding

DMM received partial funding from KNH Research and Programs Department (Registration Number: Med/101/2017) to conduct this study. Website: http://knh.or.ke/. The funders had no role in study design, data collection and analysis, decision to publish or preparation of the manuscript.
