Topological states in multi-orbital HgTe honeycomb lattices

W. Beugeling1, E. Kalesaki2,3, C. Delerue2, Y.-M. Niquet4,5, D. Vanmaekelbergh6 & C. Morais Smith7

Research on graphene has revealed remarkable phenomena arising in the honeycomb lattice. However, the quantum spin Hall effect predicted at the $K$ point could not be observed in graphene and other honeycomb structures of light elements due to an insufficiently strong spin-orbit coupling. Here we show theoretically that 2D honeycomb lattices of HgTe can combine the effects of the honeycomb geometry and strong spin-orbit coupling. The conduction bands, experimentally accessible via doping, can be described by a tight-binding lattice model as in graphene, but including multi-orbital degrees of freedom and spin-orbit coupling. This results in very large topological gaps (up to 35 meV) and a flattened band detached from the others. Owing to this flat band and the sizable Coulomb interaction, honeycomb structures of HgTe constitute a promising platform for the observation of a fractional Chern insulator or a fractional quantum spin Hall phase.
The discovery of graphene has confronted us with a material that exhibits fascinating electronic properties, such as zero-mass carriers, persistent conductivity at vanishing density at the Dirac point, Klein tunnelling and an anomalous quantum Hall effect. Nevertheless, the absence of a bandgap in its spectrum prevents its use as a field-effect transistor, and its weak spin–orbit coupling (SOC) hampers the possibility to realize the quantum spin Hall effect and use it for quantum spintronics. The prospect of artificial graphene samples that display the lacking properties has motivated research in various paradigms to generate topologically non-trivial flat bands. Recently, an alternative path came from the self-assembly of semiconducting nanocrystals forming atomically coherent 2D structures with a long-range honeycomb pattern; the thickness and honeycomb period are defined by the size of the nanocrystals, which is in the range of 5 nm (refs 14, 15). Honeycomb lattices of PbSe and CdSe nanocrystals have been fabricated, with astonishing atomic coherence due to the oriented attachment of the nanocrystals. Theoretical investigations have shown that CdSe superlattices formed in such a way exhibit Dirac cones at two energies and nearly dispersionless bands. Unfortunately, these flat bands are connected to the nearby higher energy bands, and the SOC gaps in the conduction band are very small.

In this work, we propose a design for robust topological insulators that combine the properties of the honeycomb lattice and strong SOC. We consider three different types of HgTe layers with superimposed honeycomb geometry and present atomistic tight-binding (TB) calculations of their conduction band structure that we accurately describe by a 16-band effective model. Such lattices take advantage of the multi-orbital degrees of freedom in the honeycomb setup, allied to the strong SOC. The access to multi-orbital degrees of freedom allows for further manipulation of the topological properties. While the Haldane and Kane–Mele models originally concerned honeycomb lattices characterized by a single orbital per site (for example, $p_z$ in graphene) and isotropic nearest-neighbour (NN) hopping integrals between them, multi-orbital models have attracted much attention recently, in particular because they seem to be a paradigm to generate topologically non-trivial flat bands. The flat band structure opens the way to the realization of interesting strongly correlated states, such as fractional QSHF, fractional Chern insulators or ferromagnetic fractional Chern insulators. The currently proposed HgTe lattices exhibit conduction bands characterized by large topological gaps and an isolated flat band. We conclude that, depending on the position of the Fermi level, not only QSHF could be observed in these structures, but also fractional QSHF or fractional Chern insulator phases, as on-site and NN Coulomb–interaction parameters are found in the energy range required for their realization.

**Results**

**Design of the HgTe honeycomb lattices.** The three structures that we consider have in common that the [111] direction of the zincblende lattice is perpendicular to the plane. The first system is inspired by recent results obtained for nanocrystal self-assembly, that is, a graphene-type superlattice of truncated cubic nanocrystals attached via (110) facets. The second system consists of spheres connected by short cylinders, which allow us to vary the coupling between honeycomb lattice sites in a convenient way. The third system corresponds to a honeycomb array of cylinders. These two last systems may be experimentally realized by gas-phase deposition and lithography. We will show below that the multi-orbital topological effects are common to these three different structures.

The HgTe superlattices proposed here differ fundamentally from HgTe/CdTe quantum wells, where the QSHF has been predicted and experimentally observed. In the latter system, the appearance of the QSHF at the $\Gamma$ point is connected to band inversion and vanishes for quantum wells of thickness below 6 nm. Here instead, the effect occurs at the $K$ point, and it is driven by the honeycomb nanogeometry, allied to the strong SOC of the composing HgTe nanocrystals. This distinction is important because zero modes (Majoranas) bind to topological lattice defects when the bandgap opens at a non-$\Gamma$ point in the Brillouin zone, and hence, the underlying topological order can be detected by measuring the structure of the topological defect.

**Band structure of lattices of HgTe nanocrystals.** To unveil the topological properties of these systems, we have performed atomistic TB band structure calculations. We use a basis of 20 atomic orbitals on each atom of the nanocrystals, including the spin degree of freedom. The methodology is described in ref. 38 and is summarized in the Methods section. In comparison with bulk HgTe, the electronic structure of HgTe superlattices is characterized by a large bandgap due to the strong quantum confinement. Conduction and valence bands close to this gap are composed of several minibands and minigaps due to the periodic scattering of the electronic waves in the honeycomb structure.

In the following, we only discuss the physics of the sixteen lowest conduction bands (Fig. 1).

A typical honeycomb lattice composed of HgTe nanocrystals is shown in Fig. 1a and the related conduction band structure is displayed in Fig. 1c. To visualize the effects of SOC, we compare it with the band structure of the same honeycomb structure composed of CdSe (Fig. 1b). The strong SOC in HgTe gives rise to effects which are absent in CdSe. The overall behaviour of the band structure can be understood as follows. Each individual nanocrystal is characterized by two states with $s$ envelope wavefunction and six $p$ states at higher energy. In the honeycomb structure, strong coupling between the wavefunctions of neighbour nanocrystals leads to the formation of 16 bands grouped into two manifolds of four ($s$) and 12 ($p$) bands that are well separated. The $s$ bands have the same type of dispersion as the $\pi$ and $\pi'$ bands in real graphene. In the case of CdSe (Fig. 1b), these bands are spin degenerate and are connected at the $K$ and $K'$ points of the Brillouin zone, where their dispersion is linear (Dirac points). In HgTe, instead, the $s$ bands exhibit a small gap ($5.7$ meV) at the $K$ points and have a quadratic dispersion (see Fig. 1c). In addition, they are characterized by a visible spin splitting at all points of the Brillouin zone, except at $\Gamma$ and $M$. Among the 12 $p$ bands of CdSe nanocrystal superlattices, eight have a small dispersion and the other four basically behave like the (Dirac) $s$ bands. Four flat bands are built from the $p_{\pi}$ states perpendicular to the lattice, which are not very dispersive because $p_{\pi}-p_{\pi}$ ($\pi$) interactions are weak. Four other bands ($p_{\pi_{\gamma}}$, respectively above and below the $p$ Dirac band, are flat due to destructive interferences of electron hopping induced by the honeycomb geometry. In honeycomb lattices of HgTe nanocrystals, the SOC induces spin splitting, opens a large gap at $K$ in the $p$-like Dirac bands, and produces a considerable detachment of the lowest flat $p$ band from the Dirac $p$ band (Fig. 1c). The effects of the SOC are so strong that it is hardly possible to recognize the Dirac bands.

These unexpected features allow for the realization of several topological states of matter, by doping the system using a field-effect transistor or electrolyte gel gating. At zero energy, the
undoped system is a semiconductor with a trivial gap of about 0.4 eV. On doping the material with one electron per nanocrystal, the small s-like topological gap may be reached, whereas for fillings between two and three electrons per nanocrystal, the fractional quantum (spin) Hall regime may be realized at the flat band. For a doping level of four electrons per nanocrystal, one reaches the QSHE gap. At this point, we should emphasize that doping of nanocrystals with up to 10 electrons has already been demonstrated experimentally, therefore, all the interesting regimes that we discuss are at reach with the existing technology, at a simple switch of the doping level. Other examples of band structures for lattices of HgTe nanocrystals with different size or truncation factors are presented in Supplementary Fig. 1 and are discussed in Supplementary Note 1. They all show large topological gaps, especially in the p sector.

The topological properties of the bands are most transparently studied through an edge-state analysis in a one-dimensional nanoribbon. We consider a zigzag ribbon composed of 16 nanocrystals (34,740 atoms) per unit cell. Figure 2a shows that edge states are crossing the three gaps between the p bands as well as the gap between the s bands. These results also hold for armchair ribbons. In Supplementary Fig. 2a and Supplementary Note 2, we present the band structure for another nanoribbon, which has two inequivalent edges. Still, helical edge states characteristic of the QSHE are found, as shown by the 2D plots of the wavefunctions (Supplementary Figs 2b–e).

**Effective model.** The band structures resulting from the atomistic TB calculations are accurately described by a 16-band effective model (Fig. 1d), where each nanocrystal is treated as one site on a honeycomb lattice. The effective TB model is written in the basis of the four aforementioned orbitals \(s_{p_x} p_{y} p_z\) per site as

\[
H_{\text{eff}} = H_{\mu} + H_{\text{SN}} + H_{\text{ISO}} + H_{\text{RSO}}.
\]

Here \(H_{\mu}\) incorporates the on-site energies \(E_s\), \(E_{p_x}\), \(E_{p_y}\), and \(E_{p_z}\). The energy nanocrystals have a slightly different value of \(E_s\) compared with the bulk, to account for the different number of neighbours. The term

\[
H_{\text{SN}} = \sum_{(i,j)} \sum_{b,b'} c_{i,b,z}^\dagger V_{i,b,j,b'} c_{j,b',z},
\]

(1)

encodes NN hopping, where \(\langle ij \rangle\) denotes NN sites, \(z = \uparrow, \downarrow\) denotes spin and \(b\) and \(b'\) the orbitals. The coupling coefficients \(V_{i,b,j,b'}\) are expressed in terms of the hopping parameters \(V_{s,n}, V_{p,n}, V_{p,p}, V_{p,s}\), following the notations of ref. 42.

The intrinsic SOC term \(H_{\text{ISO}}\) couples the electron orbital angular momentum \(L\) and spin \(S = \sigma/2\). In the p sector, it is encoded through the on-site term \(\gamma_{i,a} L \cdot \sigma\). There is no on-site term in the s sector because the orbital angular momentum is ‘frozen’. For the same reason, in graphene, the on-site intrinsic SOC term is absent because the \(sp^2\) hybridization freezes the orbital momentum in the \(p_z\) state. However, as shown by Kane and Mele, the intrinsic SOC introduces a next-NN (NNN) hopping term, which is written as

\[
H_{\text{ISO}} = i\gamma_{i,a} L \cdot \sigma \sum_{(i,j)} \sum_{z,a} c_{i,z,a}^\dagger \sigma_{2a} \gamma_{j,z,a} c_{j,z,a}.
\]

(2)

Here the summation is over NNNS, and \(v_{ij} = \pm 1\), with the sign depending on the outer product of the two NN vectors that connect sites \(i\) and \(j\). The Rashba SOC term, proportional to the cross product of momentum and spin, \(\mathbf{p} \times \mathbf{S}\), is written as an NN hopping term

\[
H_{\text{RSO}} = i \sum_{(i,j)} \sum_{z,a,b} c_{i,b,z}^\dagger \gamma_{i,b,j,b'} [\mathbf{\hat{z}} \cdot (\sigma \times \mathbf{r}_{ij})]_{a,b} c_{j,b',z}.
\]

(3)

The coupling coefficients \(\gamma_{i,b,j,b'}\) have the same structure as the \(V_{i,b,j,b'}\) for the ordinary NN hopping and are expressed in terms of \(\gamma_{i,s,u}, \gamma_{p,p}, \gamma_{p,p}\). The \(sp\) term may be neglected due to the large energy separation between the \(s\) and \(p\) bands.
In Table 1, we present typical values for the parameters obtained numerically using least-squares fitting to the band structure of Fig. 1c. The band structure of the effective model is shown in Fig. 1d. As expected, the on-site term $\lambda_{\text{ISO}}^0$ is much larger than the NNN term $\lambda_{\text{ISO}}^0$, explaining the opening of a very large gap at the $K$ point and the detachment of the flat bands in the $p$ sector. Using the effective model, the non-trivial topology of the bands is confirmed by the calculation of the $Z_2$ topological invariant, the spin Chern number (Methods).

The effective model yields a band structure for the ribbon (Fig. 2b) in excellent agreement with the atomistic TB calculations (Fig. 2a). The red and blue colours in Fig. 2a,b indicate the expectation value $\langle y\sigma_z \rangle = \langle |\psi_i| y\sigma_z |\psi_i\rangle$, where $y$ is the coordinate perpendicular to the ribbon edges. This expectation value allows us to identify helical edge states that come in pairs with identical dispersion, opposite spin, and live on opposite edges. Both atomistic and effective TB models show that the gaps in the $s$ and $p$ sectors exhibit helical edge states, characteristic of the QSHE.

When the Rashba coupling is neglected in the effective model, all states are spin degenerate. The Rashba term induces a small splitting in energy, and tilts the spins slightly away from the perpendicular direction. In Fig. 2c, we plot the spin direction on each site of the zigzag ribbon for four sets of four edge states (two in each edge). The spin direction is always perpendicular to the edge, that is, the spin lies in the $yz$ plane if we choose the $x$ direction to be parallel to the edge. The localization of the selected states on the edges is visible from the weight of the wavefunction, indicated by the size of the circles in the figure. The colours of the circles are determined by the local value of $y\sigma_z$, and correspond to the colours in the dispersion (Fig. 2a,b). The site dependence of the spin direction leads to interesting spin textures. For the edge states, the typical spin texture is almost smooth: Going from one edge to the other, the spin direction interpolates between (almost) up and (almost) down in a rotational manner. A slight tilt of $\approx 3^\circ$ is observed for the edge states in the $p$ bands. In the $s$ bands, the tilt is stronger, similar to graphene\cite{15}. Here the spin vector at the edge site points $\approx 30^\circ$ away from the vertical. This difference in tilt can be explained by the much larger intrinsic SOC in the $p$ sector than in the $s$ one, whereas the two Rashba couplings $\gamma_{ss}$ and $\gamma_{pp}$ are of similar order of magnitude. Strictly speaking, one should denote this state a $Z_2$ topological insulator, but since the Rashba SOC is extremely small, one can think of an approximate QSHE.

### Flat band and Coulomb interactions

The large gaps in the $p$ sector are mainly due to the intrinsic SOC, which, contrarily to the Kane-Mele model, is described by an on-site term $(\lambda_{\text{ISO}}^0 = 15.8 \text{ meV})$. In particular, the intrinsic SOC separates the lowest flat band from the other $p$ bands, with large gaps, for example, $35 \text{ meV}$ in the case of Fig. 1c. This gap ranges from 13 to $36 \text{ meV}$ when we vary the nanocrystal size and shape (Supplementary Table 1).

Under partial filling of the lowest-energy flat $p$ band by electrons, fascinating phenomena such as fractional QSHE are predicted in the presence of strong correlations, when the strength of Coulomb interactions between electrons is large compared with the bandwidth and smaller or comparable to the energy gap between the flat band and the next higher one (for a recent review, see ref. \text{31}). In addition, it has been shown that also for large Coulomb interactions, a fractional Chern insulator phase cannot

---

**Table 1 | Parameters of the effective model.**

| On-site | NN hopping | Rashba SOC | Intrinsic SOC |
|---------|------------|------------|--------------|
| $\epsilon_{\text{bulk}}$ | $\lambda_{\text{ISO}}^0 = 0.365 \text{ eV}$ | $\lambda_{\text{ISO}}^0 = 0.81 \text{ meV}$ |
| $\epsilon_{\text{edge}}$ | $\lambda_{\text{ISO}}^0 = 0.370 \text{ eV}$ | $\lambda_{\text{ISO}}^0 = 1.58 \text{ meV}$ |
| $\epsilon_p$ | $\lambda_{\text{ISO}}^0 = 0.691 \text{ eV}$ | $\lambda_{\text{ISO}}^0 = 0.80 \text{ meV}$ |
| $\epsilon_p$ | $\lambda_{\text{ISO}}^0 = 0.691 \text{ eV}$ | $\lambda_{\text{ISO}}^0 = 31.1 \text{ meV}$ |
| $\epsilon_p$ | $\lambda_{\text{ISO}}^0 = 0.747 \text{ eV}$ | $\lambda_{\text{ISO}}^0$ on $s$ and $p$ orbitals, respectively. |

Parameters derived for the lattice of HgTe nanocrystals described in Fig. 1. $E_p$, $E_s$, and $E_n$ are the on-site energies on the $p$, $s$, and $n$ orbitals, respectively. In ribbons, the edge nanocrystals have a slightly different value of $E$ compared with the bulk ($E_{\text{ISO}}^0 + \gamma_{ss}^0$). $\lambda_{\text{ISO}}^0$, $\lambda_{\text{ISO}}^0$, and $V_{\text{ISO}}$ are the hopping parameters, following the notations of ref. \text{32}. $\gamma_{ss}$ and $\gamma_{pp}$ are the terms describing the Rashba SOC, following the same notations. The intrinsic SOC is defined by $\lambda_{\text{ISO}}^0$ and $\lambda_{\text{ISO}}^0$ on $s$ and $p$ orbitals, respectively.
be ruled out. We have thus calculated the on-site (U) and NN (V) electron–electron interaction energies for the honeycomb lattice of Fig. 1a, assuming two different dielectric environments around the nanocrystals (Methods). Table 2 shows that Coulomb energies are larger than the bandwidth and are comparable to the gap between p bands. Therefore, the gap sizes open the possibility to the experimental observation of strongly correlated quantum phases including the long sought fractional QSH).

Band structure for other types of HgTe lattices. To understand the effects of the electronic coupling between honeycomb lattice sites, we have studied a second type of superlattices with a simpler geometry, consisting of tangent spheres connected by horizontal cylinders (Fig. 3a,b). The HgTe spheres have their [111] axis orthogonal to the lattice plane and the cylinders are oriented along [110] directions perpendicular to [111]. Figure 3c,d,e depicts the evolution of the band structure with the ratio between the diameters of cylinders (d) and spheres (D) (see also Supplementary Fig. 3). An increase of d/D induces larger NN hopping terms, broader s and p bands and stronger sp hybridization, as shown by the deformation of the s band. It also results in a larger NNN term λISO, explaining why the non-trivial gap in the s sector only exists for d/D > 0.3. On the contrary, topological gaps are always present in the p sector, even for small values of d/D, because they are mainly determined by the on-site term λISO.

At high values of d/D (>0.7), the spin splitting of the bands in the entire Brillouin zone becomes particularly important due to increased Rashba couplings. In general, the lowest p band is rather flat and has a maximum separation from the next higher one for d/D close to 0.4–0.5. In that case, the energy separation can be as large as 35 meV (Fig. 3f). HgTe honeycomb structures with moderate coupling between lattice sites should provide the most suitable gap and band widths to observe the strongly correlated phases associated to the flatness of the bands.

In Supplementary Fig. 4, we show further results for a third type of honeycomb structure made of overlapping HgTe cylinders parallel to each other. Once again, the band structure can be described by the effective model (Supplementary Note 3, Supplementary Table 2 and Supplementary Fig. 5). In that case, the NN couplings are even stronger, there is no gap in the s sector due to a large Rashba term, but the non-trivial gap above the lowest p band remains. We can conclude that the topological effects in the p sector are robust against changes in the electronic coupling and honeycomb period.
Discussion
In summary, we have performed atomistic TB calculations of the band structure of 2D honeycomb lattices of HgTe. We demonstrate that the strong SOC of HgTe combined with the honeycomb structure results in several topological phases. The calculated band structure can be described by a honeycomb lattice model as in graphene but including multi-orbital degrees of freedom that generate in particular a topologically non-trivial flat band. By taking advantage of these features, we show that in the same structure not only the QSHE, but potentially also the elusive chiral tunnelling and the Klein paradox in graphene. Nature 438, 197–200 (2005).

In this context, for a broad field of the order of 1/3, correlations will be mainly governed by short-range effects.

Acknowledgements

This work was supported by the French National Research Agency (ANR) project ‘ETSFG’ (ANR-09-BLAN-0421-01). W.B. is funded by the Max-Planck-Gesellschaft through the visitor’s programme at MPI-PKS. E.K. acknowledges funding by the University of Luxembourg Research Office. D.V. and C.M.S. wish to acknowledge the Dutch FOM for financial support via the Programme 13DDC01 ‘Designing Dirac Carriers in Honeycomb Superlattices’. The work of C.M.S. is part of the D-ITP consortium, a programme of the Netherlands Organisation for Scientific Research (NWO) that is funded by the Dutch Ministry of Education, Culture and Science (OCW).

Author contributions

W.B., E.K. and C.D. performed the calculations. Y.-M.N. contributed to the development of the codes and methodologies. C.D., D.V. and C.M.S. supervised the project. All authors were involved in writing of the manuscript.
