The energy storage field is nowadays a highly ranking topic. This research deals with the installation and analysis of the ice storage system which combines heat pump, solar absorber, and ice storage tank (phase change material—PCM). This system uses a special kind of solar absorber—header pipes (HDP), which have no thermal isolation compared to the common solar absorber. Thanks to that the HDP, pipes can absorb thermal energy not only from the sun but also from the environment. The rain or snow also affects heat exchange. All that is provided by one technical device. The system can store thermal energy gained from the solar absorber into the ice storage tank for future usage. Research works with data from the real operation, for a period of the year covering all working phases/modes of the system. The analysis of the data led to the identification of several specific modes of the system, especially from the processes taking place in the PCM storage tank during its charging and discharging at various time stages of operation of the whole system. The installation and analysis of the ice storage system probably took place for the first time in Slovakia and Slovak Republic’s conditions. Besides, this system was not installed on a new low-energy house, but on an older family house with thermal insulation. The aim of this installation was also to demonstrate the usability of the ice storage system in an older house and potentially reduce the homeowner’s fees thanks to new technology with higher efficiency. We managed to comprehensively analyze and describe the operation of this system, which also appears to be highly efficient even in a family house with a lower energy certificate, than today’s new low-energy buildings. The results showed a significant efficiency difference in favor of the ice storage system compared to conventional heating systems. The total analysis time was 1616 h and the total efficiency of this heating system—the seasonal coefficient of performance (SCOP) was 4.4. Compared to the average SCOP 3.0 of conventional heating systems for new low-energy houses, the total efficiency increased by 46.6%. These results could therefore be considered as beneficial, especially if we take into account that this system was installed on an approximately 40-year-old family house. The analyzed ice storage system is still working today. The main goals of this paper were to describe the heat pump’s duty cycle with ice storage (PCM) based on real-life data and bring a detailed description of the heat transfer medium behavior at various phases of storing/utilizing heat in the vertical ice storage’s profile for increasing efficiency.
Keywords: ice storage system; phase change materials; thermal energy storage; renewable energy sources; heat energy accumulator; energy efficiency

1. Introduction

At present, we are seeing increasing pressure from society on the ecology and economy. A heat pump is a means of enabling the economically and environmentally justified use of a dissipated part of thermal energy for a usable purpose of heating/preparation of hot water and the like [1]. On the other hand, PCM/ice storage [2] allows the use of the potential of latent heat to store thermal energy, thanks to the combination of both principles, respectively, equipment [3]. The ice storage system is the way to store and use thermal energy [4].

The ice storage system uses water/ice in a tank solar absorber or PV panels, and heat pump. As the heat exchanger is used, the air/water type is antifreeze [5]. This technology can be used for new or existing buildings [6]. In general, it allows using the low-potential heat [7] from sources such as earth, water, air. PCM storage (ice tank) is the main part of this system [8].

The big advantage is that in addition to the classic solar thermal circuit (heat from the air and solar radiation), this system also has another circuit with the ice tank. Thanks to this, it is possible to store part of the thermal energy from renewable sources [9,10] in the ice tank for future usage. Using renewable energy sources potential is another good reason why to choose this kind of ice storage heating system [11]. The system, therefore, appears to be a potential [12,13] with low running costs, high efficiency, without adverse environmental impacts [14–16].

Water has many advantages as large heat capacity, low cost, and very common applications in the engineering field, especially in the field of heating systems, water is very beneficial. The tank is usually filled with service water, which is easy and cheap [17]. Moreover, the water behaves like PCM in the temperatures applicable in the winter and heating season [18]. PCM can gain and store thermal energy under certain circumstances. Thermal energy can be stored in three main forms, the sensible heat, latent heat, and thermo-chemical energy. The PCM offers a space how to use latent and sensible heat [19–21]. The latent heat is especially one of the most useable energy forms in the field of this type system.

Thanks to the specific heat capacity of water, it is possible to store part of the thermal energy from the sun into the tank (the ice storage) [22]. The phase change from liquid water to solid ice at 0 °C releases as much latent heat as is necessary to heat the same amount of water from 0 to 80 °C. This represents a huge amount of energy [23]. Phase transformations and the ability to extend as much as possible the time when storage behaves like PCM are a very important part of the system [24]. The specific enthalpy [25] of the phase transformation is thus relatively high compared to the specific heat capacity. For water, the fusion enthalpy is 334 kJ/kg and the specific heat capacity is 4.19 kJ/kg [26]. The result is that the energy density is considerably higher compared to hot water tanks. If one liter of water is cooled by 1 K, the 1.163 kW of energy is released [27]. While the temperature remains constant at 0 °C during icing, the additional crystallization energy (93 Wh/kg) is released, which can be used by the heat pump [28]. It follows that storing the ice into a tank has enormous energy importance. Phase conversion makes this system more efficient [29]. Energy can be extracted from the ice. As the storage volume increases, so does the stored energy capacity and the PCM phase time [30]. The results showed that the thermal storage system [31] is a highly effective system that increases the coefficient of performance (COP) heating factor [32,33].

Heat pumps efficiency is expressed in a dimensionless number as the coefficient of performance (COP). The COP is the current efficiency of the work and it could be influenced by temperature conditions during the heat pumps working cycle. The seasonal performance factor SCOP is a more valuable coefficient especially for the customer’s point of view. The SCOP is evaluated at the end of
the heating season and counts the amount of received and transferred energy. In general, is the SCOP lower than the COP, therefore, it is more important to pay attention to the SCOP.

The study of the solar-air source heat pump heating system in China in this work [34] showed the average COP of 1.95. Another simulated performance of a borehole-coupled heat pump seasonal solar thermal storage system for space heating in cold climate [35] showed the highest COP of 5.8.

These results show that the real efficiency and coefficient of performance depends on various factors, such as the locality, temperatures, conditions, working time of heat pump, and so on.

In Slovak conditions, the ice storage system has probably not yet been installed before. This is the first well-known research that deals with the real installation and analysis of the ice storage heating system with a special solar absorber, well known as the header pipes (HDP), in the east of Slovakia. Moreover, the system was installed in an older house. Identifying specificities and thorough mapping is a prerequisite where it will be possible to efficiently adapt technical solutions based on conventional systems and optimize them for the new desired function. This undoubtedly lies in the importance of this work for the further development of science and practice.

**Heating Systems Comparison**

In Figure 1, common heating systems are compared, including the ice storage system. A common heat pump uses only ambient thermal energy. The common ice storage system uses also ambient thermal energy through the PV panels or solar absorber as the heat transfer medium. The ice storage tank (PCM) serves as a type of additional energy source in which part of the thermal energy obtained by the sun can be stored for future usage. In this case, it is possible to transfer part of the thermal energy to the water/ice.

![Figure 1. Heating systems comparison.](image-url)

The combined ice storage system in this work also uses the ice storage tank (PCM) and HDP pipes as the heat transfer medium. This kind of absorber is very specific and can absorb the thermal energy not only from the sun like the PV panels/solar absorber but also from outside—by one technical device. The main difference is that HDP pipes, unlike the PV panels and solar absorber, have no thermal insulation. The rain or snow conditions also influence the thermal energy transfer.

2. Materials and Methods

The analysis of the researched combined ice storage system is based on data from real operations. The recording of data starts from 30th September 2018 at 0:00, till 5th October 2018 where data 1 data per minute were obtained. From 5th October 2018 until the end of the analysis 9th April 2019 18:00, 1
The installation of this system was provided by one Slovak company and it was the first installation. The reason why this system was installed in an older house was to ensure and demonstrate the usability of the ice storage system. The reason was also the possible reduction of fees with new technology for homeowners.

2.1. HDP Pipes—Solar Absorber

The special kind of solar absorber—HDP (header pipes) is located on the cube-shaped roof—Figure 3. The total length of the pipes is 400 m with diameter 32 mm. This absorber can receive heat not only from the sun but also from the environment. The rain or snow weather conditions also affect the thermal flowing. There may occur situations when the rain or snow could receive or transfer thermal energy from/to HDP pipes and influence the heat transfer in the system. The working substance in the circuits is a mixture of liquids (brine/water). In Figure 2, it is marked as tc—the collector (HDP absorber) temperature sensor for data capturing. Originally there were common PV panels on the roof, but before the analysis, the PV panels were exchanged for the HDP.

![Combined ice storage system scheme](image-url)
2.2. The Ice Storage Tank

The ice storage tank has 10 m$^3$ (10,000 L) volume with a cylinder shape. This volume is standard for family houses and can be extended. Extension of ice storage tanks volume can bring a longer duration of PCM phases which could have a beneficial influence on the system efficiency increment. Its location is in the garden in the place where originally the well was—in Figure 4 The tank was made to measure from a metal material. The tank was filled with service water.

![Image of HDP pipes (collectors) on the roof in winter.](image-url)

**Figure 3.** HDP pipes (collectors) on the roof in winter.

![Image of ice storage tank location.](image-url)

**Figure 4.** Ice storage tank location.

The tank temperatures originally contained 9 temperatures from which 3 sensors of temperatures were on the left edge and another 3 sensors on the right edge of the tank. Unfortunately, these sensors showed very large variations. Therefore, we evaluated only 3 temperatures from sensors located in the middle side of the tank. Temperatures and positions of the ice storage tank (t1-t3) are illustrated in Figures 2 and 5.

![Image of ice storage tank.](image-url)

**Figure 5.** Ice storage tank.

2.3. Temperatures

We captured 9 temperatures through the analysis from which we evaluated only 5 important temperatures for our research. Captured temperatures data included the outside environment temperature, absorber temperature, service water temperature, and ice storage tank temperature. We focused mainly on the ice storage tank itself.
Analyzed 5 types of temperatures were matched as:

- t1—ice storage tank temperature in the down position.
- t2—ice storage tank temperature in the center position.
- t3—ice storage tank temperature in the up position.
- to—outside (environment) temperature.
- tc—collector (HDP absorber) temperature.

2.4. Operating Modes/States of Heat Pump

During the analysis, 3 working modes of the system occurred. The heat pump controlled the operation of each condition based on temperature conditions. The operating mode controls the behavior of the system. The value of three operating modes showed only: State 1—turn on, or state 0—turn off.

1. **Status**—Solar absorber circuit: The refrigerant from the solar collectors circulates directly into the heat pump without transferring part of the thermal energy inside the ice tank. This circuit behaves like any other common heat pump without the ice storage tank. The illustration is shown in Figure 6.

2. **Status**—Charging process (Solar absorber circuit with ice tank recharging): Turns on, when the temperature difference between the tank and HDP absorber is greater than 4.25 °C. The coolant starts to transfer and store part of thermal energy from the HDP absorber into the ice tank. Thanks to that the ice/water inside the tank being heated, thermal energy is stored from the collectors for future usage. This condition turns off when the temperature difference between the HDP absorber and the ice tank drops by 3.75 °C. Status 1 and status 2 work together at the same time, but only in the case if the temperature difference between the HDP absorber and ice storage tank is greater than 4.25 °C. The illustration of this status is in Figure 7.

3. **Status**—Discharging process (Ice tank temperature circuit): Turns on, when the ice storage tank has the higher temperature than the HDP absorber. The ice storage becomes the warmest and also the primary energy source of the system. The collector pump turns off and thanks to the three-way valve, the fluid circulated only from the heat pump to the ice storage tank. We use stored thermal energy in the water/ice. This status represents the ice storage usage and turns off when the temperature of the HDP absorber is higher than the ice storage tank temperature. The illustration is shown in Figure 8.

![Figure 6. The first status of the heat pump.](image-url)
The heat pump itself calculates the flows of received and transferred energy. The total efficiency—seasonal coefficient of performance (SCOP) of this system was evaluated by the heat pump controller at the end of the analysis. It is necessary to note, that coefficient of performance (COP) is the current efficiency of the heating system. The seasonal coefficient of performance (SCOP) is efficiency from all seasons (working time), which is more valuable especially from the customer’s point of view. The COP and SCOP were calculated by the heat pump at the same time. Our analysis aims to better understand how this system works, better describe the relationships between graphical/numerical input and real conditions. The goal was also to bring a detailed description of the heat transfers medium behavior at various phases of storing and using thermal energy in the vertical ice storage tank profile to increase efficiency.

Figure 7. The second status of the heat pump.

Figure 8. The third status of the heat pump.
2.6. Ice Storage Phases

Before the analysis, we suggested that the expected phases of the ice tank are based on the theoretical knowledge of water. In Figure 9, we can see the expected phases of ice storage. Depending on temperatures, we supposed 4 phases of the ice storage tank. The water has many anomalies, especially in the temperature range from 0 to 4 °C when behavior is opposite than would we expected. The most interesting phase is the third PCM phase, which is also the most significant for the analysis. All these phases need to be taken into account for analysis.

During the analysis, some unpredictable and interesting moments occurred, which are better described and illustrated in the results. These moments are important for a better understanding of the whole working process of the system, especially the states and properties of ice storage itself.

3. Results and Discussion

In this research, 775,496 data were analyzed. The total analysis time was 192 days, including the key part of the heating season. During that time, all expected phases of the ice storage tank occurred. In the results, are provided all ice storage phases, temperature courses, anomalies, and other interesting moments occurred during the analysis.

3.1. Temperature Process throughout Data Collection

Figure 10 shows the temperature profile of all temperatures investigated throughout the data collection. The graphical sequence corresponds to the temperatures to and tc. It can be said that the temperature conditions varied depending on the season and temperatures of particular days and months. It is certainly worth mentioning the period of freezing water and melting ice. The freezing occurred in December and ice melting in March and continued until April 2019.
3.2. Heating System Processes Overview

The course of heat pump operation for the entire data collection period is shown in Figure 11. The most common was state 2—solar absorber circuit + ice charging, up to 43.7% and 706.07 h of data collection, respectively. The usage of thermal energy from the ice storage (state 3) was 20.32% and 328.25 h, which represents one-fifth of the total time of data collection.

3.3. Ice Storage States

The tank has been divided into 3 positions based on sensors and as we can see, the results are not uniform. The tank states and their time depends on the position. Individual states are shown
in Figures 12–14. We can say that most often there was ice in the tank. The second most common condition was 4+ when the water was in a normal stratification state.

3.3.1. Down Position t1:

Ice storage states in down position are shown in Figure 12.

![Figure 12. Ice storage states of t1—down position.](image)

3.3.2. Middle Position t2:

Ice storage states in middle position are shown in Figure 13.

![Figure 13. Ice storage states of t2—middle position.](image)

3.3.3. Upper Position t3:

Ice storage states in upper position are shown in Figure 14.

![Figure 14. Ice storage states of t3—upper position.](image)
According to Figures 12–14, the upper position—t3 temperature first began to freeze. The second was t2 temperature in the middle position and the last was the t1 in the down position.

The melting process shows the opposite results. The first one melted was the t1—down position. The second was the middle position t2 and finally the last was the up position t3.

It is interesting that the water behaves in the opposite way that would we expect in common fluids. In the same way, these graphs in Figures 12–14 show that our assumption of phase separation based on water properties was correct.

3.4. Overall View of Temperatures

The graphical output of all analyzed temperatures from the whole research period is shown in Figure 15.

Figure 15. Overall view of temperatures.

Together we examine 5 temperatures from the temperature sensors of the combined heating system. We can see how temperatures dropped down depending on the season and vice versa, their
increment in warmer months. The temperature also affects the heat pumps efficiency and its operating states. Based on Figure 15, we can see that the temperature of ice storage depends on the HDP temperature and the HDP temperature at the same way depends on the outside temperature.

3.4.1. First Phase—Normal Water Stratification

Figure 16 shows the first phase of the ice storage tank.

![Figure 16. I. Phase—Normal water stratification.](image)

This phase in normal water stratification behaves like any other conventional fluid. The fluctuations shown in Figure 16 are typical for charging and using the ice storage during days and nights when it behaves as the primary thermal energy source.

3.4.2. Second Phase—Inverse Water Stratification (Water Anomaly)

The graph in Figure 17 shows an anomaly caused by the properties of the water, indicated in the blue circle.

![Figure 17. II. Phase—Inverse water stratification.](image)
As soon as the water temperature reaches 4 °C (more accurate, it is 3.98 °C), the water starts to behave oppositely than would we expect in common fluids. This phenomenon is caused by the changing of water density. Based on the graph, we can see that the lines turned in the opposite direction. From this point, the warmer water stays located at the bottom. This anomaly is very important not just for our analysis but also for everyday life. The fact that water starts to freeze on the top, and the bottom is still liquid and warm, is, for example, vital for the aquatic animals in nature. Without this anomaly, aquatic animals would not be able to survive in water.

3.4.3. Third Phase—Freezing in Upper Position

The graph in Figure 18 show freezing in the upper position t3.

![Figure 18. III. Phase: 0—Freezing in upper position t3.](image)

From 7 December 2018, shows the freezing at the t3 position (the lowest red line), indicating with a minus temperature. This is the most important phase for our research. This phase is releasing the energy which is better known as the latent heat with value 334 kJ/kg. If we think about the volume 10 m³ (10,000 L water) in the ice storage tank, we can say that is a huge amount of energy-releasing. If we would take into account that 1 L of water equals approximately 1 kg in our computation, then approximately 3,340,000 kJ will be released.

3.4.4. Fourth Phase: Solid-State

Figure 19 shows the solid state.

![Figure 19. IV. Phase: 0—Solid state.](image)
The temperatures t1–t3 dropped below freezing. Temperature t3 in the up position showed the highest temperature of approximately −2.94 °C from 11 December 2018. Based on results, it is clear that the tank has since this date entered the solid state (ice). Moreover, there are some other changes. The specific heat capacity of the working substance is now lower. The specific heat capacity of ice is approximately 2.1 kJ/kg, which is half compared to water 4.2 kJ/kg. The transfer of thermal energy has also changed from flowing to conduction.

3.4.5. Third Phase—Melting Process

Figure 20 shows melting process.

Figure 20 represents the long-term graph of the melting process in the solid phase of the tank. During this phase, one interesting moment occurred, when the temperatures drop down so rapidly, the melting process stopped for a short time and began to freeze back (indicated in the circle).

This phase is a little bit complicated compared to freezing because the ice inside the tank now must receive latent heat for melting.

3.4.6. Third Phase—Melting in Down (t1) Position

The graph in Figure 21 describes the first ice melting of temperature t1 in the down position. The melting occurred on March 21st, 2019 at approximately 16:10 and showed a temperature t1 of approximately 2.6 °C, and the ice turned to water. The ice melted first in the down position, which we also assumed based on the water’s properties, as the temperature during melting should have the highest temperature in the down position.
3.4.7. Third Phase—Melting in Middle (t2) Position

Melting in the middle position—t2 occurred in Figure 22, on 1 April 2019.

3.4.8. Third Phase—Melting in Upper (t3) Position

On 8 April 2019, melting of the ice in the last up position occurred—t3 which is graphically shown in Figure 23 (the green circle). From 8 April 2019, the ice melted to water and the entire tank went back into the first phase 4+. As we can see in Figure 23, the temperature rising is so fast, that we jumped from 3rd phases back to the 1st phase in a very short time. Temperatures from that time showed positive temperatures and the ice storage tank was back in a normal stratification state.
3.4.9. First Phase—Normal Water Stratification 4+

Figure 23. III. Phase—Melting ice t3.

Figure 24 shows again the First Phase.

Figure 24 shows the ice storage tank with positive temperatures approximately 11 °C. We can also see that the t3 (up position) is now the highest and the t1 (down position) is again the lowest. The usage of the ice storage tank does not end. From that moment, the tank could be used for cooling if the analyzed house was modified for this purpose.

As we can see in Figure 24, the temperatures were already in the range from 4 °C and higher (normal stratification). But according to Viewdet graphical output, the t3 (up position) began to show the highest temperature later than would we expected. It was on April 9, 2019, approximately between
4. Conclusions

The beginning of data recording started on 30 September 2018, at 00:00. The end of the data recording was on 9 April 2019, at 18:00. The total number of data obtained was 1,163,244, of which 775,496 data were analyzed. The total time of analysis was 192 days. The freezing time lasted for 14 days. The melting process lasted for 32 days, which means that the melting itself is more complicated. The total time of PCM behavior was 46 days.

The results point to the fact, that the transformation of the ice tank itself plays an important role. It has been shown that this tank is characterized by good thermal insulation against environmental and collector temperature changes. On the other hand, it needs to be taken into consideration that the water in the tank is a fluid with different movements. During different ice storage phases, the temperature sensors could be influenced by water flowing. In other words, in freezing phase (temperatures from 4 °C to 0 °C), the warmer water flows down and the cooler water vice versa up. These movements could have affected the measurement and temperature rising or falling in sensors located in the down (t1), middle (t2, and up position (t3). The same situation could influence the sensors during the melting phase. Measured data and measurement results can also be affected in this way. This consideration is also supported by the fact that the freezing/melting did not appear in the ice tank at the same time and in the same position. This is also the reason why we divided the tank into 3 positions and why we anticipated it. Taking into account the volume of the tank 10 m³ (10,000 L), it should be noted that it would be appropriate to examine these unpredictable phenomena in more detail. For example, the most likely solution would be to use a camera system in the tank to capture these facts and better identify them.

The main benefit of this research for theory is real captured data analysis. Benefit for praxis is that we can better understand how this ice storage system with HDP pipes works, especially at the various phases of storing and using thermal energy in the vertical profile of the ice tank for energy efficiency increment. At the same time, research creates space for further continuation of this issue. It would be beneficial to analyze this combined heating system with the ice storage tank for at least one year of operation, possibly over a longer period. The system could also be used as an air conditioner. To do this, it would be necessary to switch off the charging circuit (2nd operating state) and leave only the ice tank circuit on (3rd operating state). This could potentially be another research. The other idea could be the comparison of this system with the ice storage and HDP solar absorber between this older house and a new low-energy type house or building. A suitable alternative would also be to map the operating fluid flows in real time. In this way, we would also record the amount of energy received and transferred to the system. It would be also beneficial to compare operating costs of house before and after installation.

The overall efficiency—the seasonal coefficient of performance (SCOP) of the heating work was determined by the heat pump with value 4.4. The average SCOP of heating systems is approximately 3.0 which represents the average efficiency increase in favor of the ice storage system with HDP solar absorber by 46.6%.

However, it should be noted that during winter, the current COP at that time ranged from 7–8, which makes this system more profound and interesting. The COP of heating systems ranges from 3–5.5, which is up to 145–233% more beneficial compared to conventional heating systems efficiency. The results therefore showed that this system has the highest efficiency during winter with minus temperatures.

We must say, that probably the final SCOP coefficient 4.4 would be probably higher, but our system, and especially heat pump, was working all 192 days without a break. The reason why is because the system was set up to store thermal energy from the environment for ice storage, whenever the temperature conditions allowed it. In our case, it was the temperature difference higher than 4.25
°C between the HDP absorber and ice tank. Of course, when the heat pump was working, it also consumed part of the energy. If we customized the heat pump better and better adjusted the 2nd operating state of storing thermal energy in the ice tank, the system would probably be more efficient. This also could be the idea for the next research. Taken into account all of this, we can consider the ice storage system installation with special kinds of the solar absorber (HDP pipes) in the 40-year-old house as beneficial. Moreover, if this ice storage system with HDP solar absorber could effective work in an older house, it definitely must work much more effective in new low-energy houses.
