We report on the discovery of high-energy (HE; \( E > 0.1 \) GeV) and very high energy (VHE; \( E > 100 \) GeV) \( \gamma \)-ray emission from the high-frequency-peaked BL Lac object RBS 0413. VERITAS, a ground-based \( \gamma \)-ray observatory, detected VHE \( \gamma \) rays from RBS 0413 with a statistical significance of 5.5 standard deviations (\( \sigma \)) and a \( \gamma \)-ray flux of \((1.5 \pm 0.6_{\text{stat}} \pm 0.7_{\text{sys}}) \times 10^{-8} \) photons m\(^{-2}\) s\(^{-1}\) (\( \sim 1\% \) of the Crab Nebula flux) above 250 GeV. The observed spectrum can be described by a power law with a photon index of 3.18 \( \pm 0.68_{\text{stat}} \pm 0.30_{\text{sys}} \). Contemporaneous observations with the Large Area Telescope (LAT) on the Fermi Gamma-ray Space Telescope detected HE \( \gamma \) rays from RBS 0413 with a statistical significance of more than 9\( \sigma \), a power-law photon index of 1.57 \( \pm 0.12_{\text{stat}} -0.12_{\text{sys}} \), and a \( \gamma \)-ray flux between 300 MeV and 300 GeV of \((1.64 \pm 0.43_{\text{stat}} +0.31_{\text{sys}} -0.22_{\text{sys}}) \times 10^{-5} \) photons m\(^{-2}\) s\(^{-1}\). We present the results from Fermi-LAT and VERITAS, including a spectral energy distribution modeling of the \( \gamma \)-ray, quasi-simultaneous X-ray (Swift-XRT), ultraviolet (Swift-UVOT), and \( R \)-band optical (MDM) data. We find that, if conditions close to equipartition are required, both the combined synchrotron self-Compton/external-Compton and the lepto-hadronic models are preferred over a pure synchrotron self-Compton model.

**Online-only material:** color figure
1. INTRODUCTION

Blazars are active galactic nuclei that have their jet axis oriented at a small angle with respect to the observer (Urry & Padovani 1995). They are observationally classified as either flat-spectrum radio quasars (FSRQ) or BL Lacertae (BL Lac) objects according to the broad line emission in their optical spectra. Recent studies interpreting the differing spectral high-energy (HE) γ-ray properties of the FSRQs and BL Lacs based on physical mechanisms can be found in, e.g., Ghisellini et al. (2009). Blazars are known to emit non-thermal radiation characterized by a double-peaked spectral energy distribution (SED). The low-energy component, generally covering radio to UV/X-ray bands, is usually explained as due to synchrotron emission from relativistic electrons in the blazar jet. The origin of the HE component, occurring in the X-ray to γ-ray regime, is still not completely resolved and could be due to emission from a relativistic particle beam consisting of leptons and/or hadrons. In leptonic models, very high energy (VHE) photons are produced by inverse-Compton (IC) scattering of low-energy photons off the synchrotron-emitting electrons. The soft seed photons for the IC process can be the synchrotron photons (synchrotron self-Compton (SSC); e.g., Maraschi et al. 1992), or they may originate from ambient radiation (external-Compton (EC); e.g., Dermer & Schlickeiser 1993). Hadronic models include synchrotron emission from protons (e.g., Aharonian 2000) and π0-decay from hadronic interactions with subsequent electromagnetic cascades (e.g., Mücke et al. 2003).

RBS 0413 was discovered in the X-ray band (1E 0317.0+1834) during the Einstein Medium Sensitivity Survey and was optically identified as a BL Lac (Gioia et al. 1984). The object was also detected as a radio emitter with the Very Large Array of the National Radio Astronomy Observatory (Stocke et al. 1990). It exhibits significant and variable optical polarization (Stocke et al. 1985). Having a “featureless” optical spectrum (Stocke et al. 1989) and an estimated synchrotron peak frequency log (νpeak/Hz) = 16.99 (Nieppola et al. 2006), RBS 0413 is classified as a high-frequency-peaked BL Lac object (HBL; Padovani & Giommi 1995). It is located at a redshift of 0.190 (Gioia et al. 1984; Stocke et al. 1985).

The MAGIC Collaboration observed RBS 0413 in 2004 December–2005 February for a livetime of 6.9 hr and reported a VHE flux upper limit of 4.2 × 10−12 erg cm−2 s−1 at 200 GeV, assuming a power-law spectrum with a photon index of 3.0 (Albert et al. 2008). VERITAS observed the source in the 2008–2009 season and obtained a marginal significance of ∼3σ. In 2009, Fermi Large Area Telescope (LAT) detected HE emission from the direction of RBS 0413 (Abdo et al. 2010b), triggering new VERITAS observations. These new observations, combined with the previous data, resulted in the detection of RBS 0413 as a VHE γ-ray emitter in 2009 October (Ong & Fortin 2009).

2. VERITAS OBSERVATIONS AND ANALYSIS RESULTS

VERITAS is a ground-based γ-ray observatory sensitive to γ rays with energy between 100 GeV and 30 TeV. Located at the Fred Lawrence Whipple Observatory (FLWO) near Amado, southern Arizona, USA (1.3 km above sea level, N 31° 40′, W 110° 57′), the array consists of four imaging atmospheric Cherenkov telescopes, each having a diameter of 12 m and a field of view of 3.5′ (Holder et al. 2008). During the 2009 annual shutdown (July–August), one of the telescopes was relocated to give a more symmetrical array layout. In addition, a new mirror-alignment system applied in 2009 Spring contributed to an improvement in the point-spread function (PSF), with a decrease of 25%–30% in the 80% containment radius (McCann et al. 2010). As a consequence, the sensitivity showed a significant improvement, and the observation time required for a 1% Crab Nebula detection dropped from ∼48 hr to less than 30 hr. For observations at 70° elevation, the energy resolution is 15%–20%, and the angular resolution, defined as the 68% containment radius, is less than 0.1′ (Perkins et al. 2009).

VERITAS observed RBS 0413 for 48 hr total using wobble mode (Aharonian 2001), with north, south, east, and west wobble positions. After discarding observing runs compromised by bad weather, and a small number affected by hardware problems, 26 hr remained for analysis. One-third of these data were obtained with the old array configuration (2008 September–2009 February, MJD 54732–54883) and the rest with the new array (2009 September–2010 January, MJD 55092–55485). Approximately 3 hr of data with the old array were taken under weak moonlight, which leads to a higher energy threshold for those observations. The source elevation in the data set ranges from 57° to 79°, with an average of ∼70°. Data analysis steps consist of calibration, image parameterization (Hillas 1985), event reconstruction, background rejection, and signal extraction as described in Daniel et al. (2008). For signal extraction, a θ2 cut (Daniel et al. 2008) of 0.0169, optimized for a point source of 1% strength of the Crab Nebula, was used.

RBS 0413 is a weak source in the VHE regime. Using a “reflected-region” background estimation (Aharonian 2001), an excess of 180 events and a significance of 5.5σ are obtained for the source location at R.A. = 03h19m47s ± 0.60 (stat) ± 0.85 (syst) and decl. = 18°45′7″ ± 1.2 (stat) ± 1.8 (syst) (2000 coordinates). The VERITAS signal is consistent with a point source, and we name the object VER J0319+187. The energy distribution of γ-ray events extends from ∼250 GeV to ∼1.0 TeV (see Table 1 for a list of spectral data points) and is well described by a power-law function, dN/dE = F0E−Γ. The best fit is obtained with photon index Γ = 3.18 ± 0.68(stat) ± 0.30(syst) and flux normalization F0 = (1.38 ± 0.52(stat) ± 0.60(syst)) × 10−7 TeV−1 m−2 s−1 at 0.3 TeV, with a value of χ2 per degree of freedom (χ2/ν) of 0.14/2 (see Figure 1).

The integral flux above 250 GeV is (1.5 ± 0.6(stat) ± 0.7(syst)) × 10−8 m−2 s−1, corresponding to a flux level of approximately 1% of the flux of the Crab Nebula. No significant flux variability is detected (see Figure 2, top panel and caption for details of the light-curve analysis). An upper limit (99% confidence level) on the fractional variability amplitude (Fvar; Vaughan et al. 2003) yields Fvar < 3.2.

3. FERMI OBSERVATIONS AND ANALYSIS RESULTS

The LAT aboard the Fermi Gamma-ray Space Telescope is a pair-conversion γ-ray detector sensitive to photons in the energy

| Energy (TeV) | Flux (m−2 s−1 TeV−1) | Significance (σ) |
|-------------|----------------------|------------------|
| 0.30        | (1.3 ± 0.7) × 10−7   | 2.1              |
| 0.42        | (5.1 ± 1.9) × 10−8   | 3.0              |
| 0.60        | (1.5 ± 0.7) × 10−8   | 2.3              |
| 0.85        | (4.3 ± 3.4) × 10−9   | 1.2              |

**Notes.** The first column shows the mean energies, weighted by the spectral index. The errors are statistical only.
range from below 20 MeV to more than 300 GeV (Atwood et al. 2009). The present analysis includes the data taken between 2008 August 4 and 2011 January 4 (MJD 54682–55565), which covers the entire VERITAS observation interval. Events from the Pass 6 diffuse class with energy between 300 MeV and 300 GeV, with zenith angle $< 100^\circ$, and from a square region of side 20$^\circ$ centered on RBS 0413, were selected for this analysis. The cut at 300 MeV was used to minimize larger systematic errors at lower energies. The time intervals when the source was close to the Sun (MJD 54954–54974 and 55320–55339) were excluded. The data were analyzed with the LAT Science Tools version v9r20p6 and the post-launch instrument-response functions P6_V11_DIFFUSE. The binned maximum-likelihood tools were used for significance and flux calculation (Cash 1979; Mattox et al. 1996). Sources from the 1FGL catalog (Abdo et al. 2010b) located within a square region of side 24$^\circ$ centered on RBS 0413 were included in the model of the region. The background model includes the standard Galactic and isotropic diffuse emission components.

A point source positionally consistent with RBS 0413 is detected with a significance of more than 9$\sigma$ (test statistic, TS = 89; see Mattox et al. 1996). The photon energy spectrum is best described by a power-law function. Replacing the power-law model with a log-parabola model does not significantly improve the likelihood fit. The time-averaged integral flux is $I(300\,\text{MeV} < E < 300\,\text{GeV}) = (1.64 \pm 0.43_{\text{stat}} \pm 0.31_{\text{sys}}) \times 10^{-5}\,\text{m}^{-2}\,\text{s}^{-1}$, and the spectral index is $1.57 \pm 0.12_{\text{stat}} \pm 0.11_{\text{sys}}$.

The spectral points were calculated using the procedure presented in Abdo et al. (2010b; see Table 2). In the energy range 100–300 GeV, no detection was obtained (TS $< 9$) and an upper limit at the 95% confidence level was derived. Figure 2 (bottom panel) shows the Fermi light curve with $\sim$6 month wide time bins. The upper limit point in the last time bin has a 95% confidence level.

---

**Figure 1.** VERITAS measured photon spectrum of RBS 0413. See the text for the parameters of the power-law fit shown.

**Figure 2.** Top: 30 day light curve for the VERITAS data. A fit with a constant function gives a $\chi^2$/dof value of 14/8, corresponding to a fit probability of 8%, consistent with the hypothesis of a constant flux. The negative flux point corresponding to the upper limit point in the light curve was included in the fit. Bottom: the light curve for the Fermi data using $\sim$6 month wide time bins. The shaded areas represent the time intervals that were excluded to avoid solar contamination. In both graphs, the dashed lines represent the constant fit function.

The latest response matrix from the XRT calibration files was extracted from a 40 pixel radius circle in a source-free region. Ancillary response files were generated using the tool xrtmkarf task, moving within a circular region with a radius of 30 pixels.”}

Notes. The energies correspond to the bin centers. The errors are statistical only.

4. SWIFT OBSERVATIONS

The VERITAS detection triggered a Swift (Gehrels et al. 2004) target-of-opportunity observation of RBS 0413 on 2009 November 11, with a total exposure of 2.4 ks. All Swift–XRT data were reduced using the standard Swift analysis pipeline described in Burrows et al. (2005) using the HEAsoft 6.8 package. Event files were calibrated and cleaned following the standard filtering criteria using the xrtpipeline task and applying calibration files current to 2010 March. All data were taken in photon-counting mode over the energy range 0.3–10 keV. Due to the moderate count rate of 0.3 counts s⁻¹, the data are not affected by photon pile-up in the core of the PSF, and partial masking of the source is not necessary. Source events were extracted from a circular region with a radius of 30 pixels (70′′) centered on the source, and background events were extracted from a 40 pixel radius circle in a source-free region. Ancillary response files were generated using the xrtmkarf task, with corrections applied for the PSF losses and CCD defects. The latest response matrix from the XRT calibration files was applied. The extracted XRT energy spectrum was rebinned to contain a minimum of 20 counts in each bin.

An absorbed power-law model, including the phabs model for photoelectric absorption, was fitted to the Swift–XRT photon spectrum. The cross-sections and abundances used the standard Xspec v12.5 values, as given in the Xspec Analysis Manual.

Using a fixed Galactic hydrogen column density, $N_H = 8.91 \times 10^{20}$ cm⁻² (Kalberla et al. 2005), the best-fit model yields a $\chi^2$/dof value of 25.9/26. Over the energy range 0.3–10 keV, the best-fit photon index is $\Gamma = 2.22 \pm 0.07$, and the normalization at 1 keV is $(33.1 \pm 2.2)$ keV⁻¹ m⁻² s⁻¹. The unabsorbed integral flux is $F(0.3–10 \text{ keV}) = (1.69 \pm 0.12) \times 10^{-11}$ erg cm⁻² s⁻¹ in the range 0.3–10 keV. The absorbed integral flux in the range 2–10 keV is $F(2–10 \text{ keV}) = (5.81 \pm 0.55) \times 10^{-12}$ erg cm⁻² s⁻¹. No flux variability is evident over the 2.4 ks exposure.

UVOT observations were taken in the photometric band $UVM2$ (2246 Å; Poole et al. 2008). The uvotsource tool was used to extract counts, correct for coincidence losses, apply background subtraction, and calculate the source flux. The standard 5″ radius source aperture was used, with a 20″ background region. The source fluxes were dereddened using the procedure in Roming et al. (2009). The measured flux is $(2.75 \pm 0.11) \times 10^{-12}$ erg cm⁻² s⁻¹.

5. MDM OBSERVATIONS

The R-band optical data were taken with the 1.3 m McGraw-Hill telescope at the MDM observatory on Kitt Peak, Arizona, between 2009 December 10 and 13. All frames were bias corrected and flat fielded using standard routines in IRAF (Barnes 1993), and instrumental magnitudes of RBS 0413 and six comparison stars in the same field of view were extracted using DAOPHOT (Massey & Davis 1992) within IRAF. Physical magnitudes were computed using the physical R-band magnitudes of the six comparison stars from the NOMAD catalog (Zacharias et al. 2005), assuming that the magnitudes quoted in that catalog are exact, then they were corrected for Galactic extinction using extinction coefficients calculated following Schlegel et al. (1998), taken from NED and converted into $\nu F_\nu$ fluxes. The flux shows variations of up to ~30% from day to day, with an average of $(2.47 \pm 0.02) \times 10^{-12}$ erg cm⁻² s⁻¹. In the case of RBS 0413, the host galaxy is expected to make a substantial contribution to the observed R-band flux. We have taken this into account in our SED modeling by adding a phenomenological host galaxy SED to our model.

6. MODELING AND DISCUSSION

The non-thermal continuum of RBS 0413 exhibits a double-peaked shape, as is typical for blazars. In this study, we applied three different time-independent models to the observed SED, using the contemporaneous X-ray, UV, and optical (R-band) data to complement the Fermi-LAT and VERITAS observations (see Figure 3). It should be noted that these observations were not strictly simultaneous. For all of the models, the emission region was assumed to be a spherical blob of size $R_{\text{b}}$, moving within the jet with a bulk Lorentz factor $\Gamma$. $R_{\text{b}}$ was constrained using the optical minimum variability timescale $\log(M_{\text{min}}) = 3.75$ (Xiang & Dai 2007), where $M_{\text{min}}$ is in units of seconds. The angle between the line of sight of the observer and the jet axis, represented by $\theta_{\text{obs}}$, was chosen to be equal to 1/\Gamma. This is referred to as the critical or superluminal angle, for which the Doppler factor equals $\Gamma$. The synchrotron emission was assumed to originate from relativistic electrons with Lorentz factors distributed between $\gamma_{\text{min}}$ and $\gamma_{\text{max}}$, following a power law with a spectral index $\delta_{\nu}$, under the influence of a magnetic field $B$.

The particle-escape timescale is represented by $t_{\text{esc}} = \eta_{\text{esc}} R_{\text{b}} / c$, where $\eta_{\text{esc}}$ is the particle-escape parameter. For each model, the parameters were adjusted to describe the data and achieve an equilibrium between the acceleration of the injected particles, the radiative cooling, and the particle escape. The best-fit parameters were used to calculate the relative partition between the magnetic field energy density and the kinetic luminosity of relativistic particles ($\epsilon_{\text{B, p}} \equiv L_{\text{B}} / L_{\text{p}}$) for each model. All model spectra were corrected for extragalactic background light (EBL) absorption using the model of Finke et al. (2010). For the

37 I.R.A.F. is distributed by the National Optical Astronomy Observatory, which is operated by the Association of Universities for Research in Astronomy (AURA) under cooperative agreement with the National Science Foundation.
optical band, a phenomenological SED reproducing the archival host galaxy spectral points was added to the model.

The first model we applied assumed a pure SSC scenario. The magnetic field energy density required in this model is only 6% of the value corresponding to equipartition with the relativistic electron distribution ($\epsilon_B = 0.06$). The model spectrum is too hard in the Fermi band (strongly curved, with $\Gamma \sim 1.5$ around $10^{23}$ Hz) and too soft in the VERITAS band ($\Gamma = 4.0$), albeit within the errors in both cases. On the other hand, while the X-ray measurements are well reproduced, the optical (R-band) spectrum is not.

Next, we tested a combined SSC+EC model. The external source of photons was assumed to be an isotropic thermal blackbody (BB) radiation field, which may be due to a torus of warm dust with a temperature of $T_{\text{ext}} = 1.5 \times 10^3$ K. The assumed BB infrared (IR) radiation field corresponds to a flux of $\sim 5 \times 10^8 \times R_p^2$ Jy Hz, where $R_p$ is the characteristic size of the IR emitter in units of parsecs. It should be noted that this quantity is far below the measured IR flux, thus consistent with our observations. The addition of an EC component improves the modeling for the optical and Fermi data compared with the pure SSC model and leads to values for the model parameters which are very close to equipartition ($\epsilon_B = 1.20$). However, the model tends to have too sharp a cutoff in the VHE band and therefore underpredicts the VERITAS flux measurements. This could be remedied by choosing a much weaker magnetic field and higher electron energies, but the resulting system would then be very far from equipartition, with $\epsilon_B$ reduced by at least two orders of magnitude.

The last model we tested is a combined lepto-hadronic jet model as described in Böttcher (2010). In this case, the HE component of the non-thermal emission is dominated by a
combination of synchrotron radiation from ultrarelativistic protons \( (E_{\text{max}} \gtrsim 10^{19} \text{ eV}) \) and photons from the decay of neutral pions. Secondary electrons that are produced in various electromagnetic cascades are the origin of the low-energy synchrotron emission. The kinetic energy of the relativistic proton population was assumed to have a single power-law distribution in the energy range \( 1.0 \times 10^{3} \text{ GeV} < E_{\gamma} < 1.6 \times 10^{10} \text{ GeV} \), with a spectral index of \( q_{\gamma} = 2.4 \). The model is a good description of the overall SED, and the system is close to equipartition between the magnetic field and the total relativistic particle content dominated by protons \( (e_{Bp} = 0.95) \). As is typical for lepto-hadronic models, the acceleration of protons to ultrarelativistic energies \( (\sim 10^{10} \text{ GeV}) \) requires a high magnetic field, 30 G in this case. Although the lepto-hadronic model provides the best description for the data, it has two more free parameters than the SSC+EC model and is therefore less constraining. The best-fit parameters adopted for all three models are summarized in Table 3.

Based on our calculations, all three models are good at describing the observed data. It appears that if the criterion of equipartition is taken as a reasonable measure of successful blazar emission models, SSC+EC is preferred over SSC for this HBL, which seems to be in contrast with some previous blazar studies. See Ghisellini et al. (1998) for arguments relating the presence of an EC component with the blazar sequence and Abdo et al. (2010a) for a discussion of issues encountered in explaining blazar SEDs with a simple one-zone homogeneous SSC model. On the other hand, we cannot discriminate between leptonic and lepto-hadronic mechanisms, since the SSC+EC and lepto-hadronic models provide equally reasonable descriptions for the observed non-thermal continuum, and we did not detect variability in the HE and VHE regimes given the limited statistics. Since the synchrotron cooling timescales for electrons and protons are different, the detection of intraday variability would be harder to explain with a lepto-hadronic scenario and would accordingly favor a purely leptonic scenario. Therefore, any future observation of rapid variability would be helpful in distinguishing between the SSC+EC and lepto-hadronic models.

The VERITAS research is supported by grants from the US Department of Energy Office of Science, the US National Science Foundation, the Smithsonian Institution, and the NASA Swift Guest Investigator Program, by NSERC in Canada, by Science Foundation Ireland (SFI 10/RFP/AST2748), and by STFC in the UK. We acknowledge the excellent work of the technical support staff at the FLWO and at the collaborating institutions in the construction and operation of the instrument.

The Fermi-LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique/Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden. Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France.
