Combined analysis of immunostaining for various biological molecules coupled with investigations of ultrastructural features of individual cells is a powerful approach for studies of cellular functions in normal and pathological conditions. However, weak antigenicity of tissues fixed by conventional methods poses a problem for immunoassays. This study introduces a method of correlative light and electron microscopy imaging of the same endocrine cells of compact and diffuse islets from human pancreatic tissue specimens. The method utilizes serial sections obtained from Epon-embedded specimens fixed with glutaraldehyde and osmium tetroxide. Double-immunofluorescence staining of thick Epon sections for endocrine hormones (insulin and glucagon) and regenerating islet-derived gene 1 α (REG1α) was performed following the removal of Epoxy resin with sodium ethoxide, antigen retrieval by autoclaving, and de-osmification treatment with hydrogen peroxide. The immunofluorescence images of endocrine cells were superimposed with the electron microscopy images of the same cells obtained from serial ultrathin sections. Immunofluorescence images showed well-preserved secretory granules in endocrine cells, whereas electron microscopy observations demonstrated corresponding secretory granules and intracellular organelles in the same cells. In conclusion, the correlative imaging approach developed by us may be useful for examining ultrastructural features in combination with immunolocalisation of endocrine hormones in the same human pancreatic islets.

Key words: correlative microscopy, Epon-embedded, compact and diffuse islets, immunostaining, hormone

I. Introduction

A large number of endocrine cells, constituting 1–2% of the total volume of the human pancreas in adults, are distributed in more than one million islets of Langerhans, first described by Paul Langerhans in 1869. The pancreatic
islets, in turn, are distributed throughout the pancreas at variable densities in different lobules, although the density in the tail portion is usually slightly higher [44]. Pancreatic islet endocrine stem cells differentiated to mature islet endocrine cells produce four major peptide hormones: insulin (β-cell granule), glucagon (α-cell granule), somatostatin (δ-cell granule), and pancreatic polypeptide (PP-cell granule), all of which show specific views by electron microscopy [8, 10, 24]. Human and rodent pancreas are developed from two different embryological origins; the dorsal origin develops the head and tail portions, whereas the ventral origin derives the head portion of the pancreas. The majority of the pancreas is derived from the dorsal anlage [8, 21, 27, 31, 38]. The islets can be classified into two types [27]. “Compact” islets comprise the majority (90%); they are covered by nests of connective tissues. Compact islets are composed of trabeculae of endocrine cells interspersed with clear capsules between adjacent pancreatic exocrine acini [17]. Other islets are “diffuse”; they have no nests separating them from adjacent exocrine acini. However, the ultrastructure supporting “diffuse” pancreatic islets including islet-encapsulating basement membranes, extracellular matrix, and adjacent exocrine acini, have not been elucidated in detail [1, 5, 6, 16, 27]. Regenerating islet-derived gene 1 alpha (REG1α) is secreted by the exocrine pancreas or β cells and affects islet cell regeneration [40, 42], thereby regulating the development of Langerhans islet architecture and diabetogenesis [1, 13, 46]. Conventional histochemical methods, such as aldehyde-fuchsin staining, Hellerstrom-Hellman silver staining, and immunohistochemical labelling of peptide hormones, are currently the major approaches used with light microscopy to directly distinguish between types of endocrine cells [10, 24]. Although examination of multiple peptide contents in combination with investigation of the ultrastructural features of individual endocrine cells would provide a detailed analyses of physiological and pathological alterations of pancreatic islets in genetically and epigenetically divergent samples such as human tissues, correlative light and electron microscopy observations combined with double-immunostaining using fluorescently-labelled secondary antibodies in the same Epon-embedded sample is an improved technique for correlative light-electron microscopy mapping which has been described before [2, 3, 23, 29, 43]. In the present study, we utilised serial sections of Epon-embedded pancreatic tissues, fixed routinely with glutaraldehyde and OsO₄, for observations with transmission electron microscopy and light microscopy following double immunofluorescence staining of endocrine cells for insulin and glucagon or for insulin and REG1α. Our results demonstrate that routinely prepared Epon-embedded samples can be utilised for correlative imaging, which allows the combined examination of ultrastructural features and the determination of endocrine hormone localisation by an immunocytochemical method in the same human endocrine cells. In this study, we focused on human heterogeneous endocrine cells found in diffuse islets immunolocalized with insulin and either glucagon or REG1α.

Finally, we confirmed the three-dimensional architecture of compact islets (tail) and diffuse islets (head) of pancreas from normal adult C57BL/6J mice by SBF-SEM [35].

II. Materials and Methods

Tissue samples

Human pancreatic tissue samples from five patients with gastric carcinoma were obtained during pancreatic resection in surgical operating rooms.

Two male C57BL/6J mice at 20 weeks of age were purchased from Charles River (Yokohama, Japan) and housed with free access to food and water, under pentobarbital anaesthesia. Pancreatic tissues obtained from both animals were taken from two different portions (head and tail).

Ethics

The Ethics Committee of the University of Yamanashi approved all the procedures performed in the present study. All patients gave their written informed consent for the collection and examination of the resected pancreas samples.

All animal experiments were approved by the Institutional Animal Care and Use Committee of National Institute for Physiological Sciences, and were performed in accordance with relevant guidelines and regulations including the “Principles of laboratory animal care” (NIH publication No. 85-23, revised 1985).

Tissue preparation for transmission electron microscopy (TEM)

Small pieces of human and mouse pancreatic tissue were prefixed with 2.5% glutaraldehyde in 0.1 M phosphate buffer (PB; pH 7.4) for 1 hr and post-fixed with 1% osmium tetroxide in 0.1 M PB for 1 hr. The specimens were routinely dehydrated by passing the tissue through a series of solutions with increasing ethanol concentrations and then embedded in Epon 812 epoxy resin. To examine the specimens, thick Epon sections were first cut at 0.5-μm thickness and routinely stained with toluidine blue (TB). These sections were checked and trimmed to visualise Langerhans islets during the next step. Then, ultrathin sections were cut at 70–80-nm thickness with a diamond knife on an ultramicrotome and mounted on Φ1 × 2 mm single slit copper grids with a formvar film covered by evaporated carbon (Fig. 1A). Then, serial 0.5-μm thick sections were cut and put on MAS-coated glass slides (Matsunami Adhesive Slides, Matsunami Glass, Osaka, Japan) for subsequent immunohistochemical staining (Fig. 1B). The ultrathin sections of human pancreas tissues on copper grids were double-stained with uranyl acetate and lead citrate and finally, observed under a H-7500 transmission electron microscope (Hitachi, Tokyo, Japan) at an accelerating volt-
Electron microscopy images and montages of Langerhans islets were edited by Photoshop imaging software (Adobe Systems Incorporated, San Jose, CA, USA).

Immunohistochemistry in serial thick sections of Epon blocks

The 0.5-μm thick Epon sections on MAS-coated glass slides were placed on a heating plate and heated to 60–80°C for 15 min. Epoxy resin was then removed from the sections by treatment with a mixture of ethoxide and absolute ethanol (1:2; v/v) for 30 min, washed in pure ethanol, and rehydrated in phosphate-buffered saline (PBS, pH 7.4). Prior to using the ethoxide/absolute ethanol mixture, saturated sodium ethoxide was aged for approximately 2 weeks until it turned dark brown [2]. Next, the specimens underwent two optional pre-treatments. For antigen retrieval pre-treatment, the specimens were autoclaved in 10 mM sodium citrate buffer (pH 6.0) at 120°C for 10 min and rinsed in PBS. In addition, to extract osmium tetroxide, the specimens were placed in 0.3% hydrogen peroxide for 10 min and rinsed in PBS.

For immunoperoxidase-3,3'-diaminobenzidine (DAB) staining, the specimens were treated with 3% fish gelatin (Sigma-Aldrich, St. Louis, MO, USA) in PBS for 10 min, followed by incubation with a guinea pig polyclonal anti-human insulin antibody (1:500–800) (A0564, Dako, Carpinteria, CA, USA), a rabbit polyclonal anti-human REG1 alpha antibody (1:200–500) (ab47099, Abcam, Cambridge, UK), or a rabbit polyclonal anti-human glucagon antibody (1:300–800) (A0565, Dako) in PBS at 4°C overnight. Immunoreactions were performed using the same procedure with the exception that incubation with the primary antibody was omitted.

The specimens were then incubated with a horseradish peroxidase (HRP)-conjugated rabbit anti-guinea pig IgG (H + L) antibody (1:400) or a goat anti-rabbit IgG (H + L) antibody (1:400; Vector Laboratories, Burlingame, CA, USA) in PBS for 1 hr and visualised by exposure to metal-enhanced DAB (Pierce, Rockford, IL, USA) for 5 min. Finally, the specimens were incubated in 0.04% osmium tetroxide in 0.1 M PB for 30 sec to enhance contrast of the DAB reaction products.

For single- or double-fluorescence immunostaining experiments, de-osmified thick sections were treated with 3% fish gelatin in PBS for 10 min, followed by a guinea pig polyclonal anti-human insulin antibody (1:400) and/or a rabbit polyclonal anti-human glucagon antibody (1:400), and a rabbit polyclonal anti-human REG1 alpha antibody (1:300) and/or an anti-human insulin antibody (1:400) in PBS at 4°C overnight. Immunoreactions were performed using the same procedure with the exception that incubation with the primary antibody was omitted.

As secondary fluorescently-labelled antibodies, we used Alexa Fluor® 594 FluoroNanogold™ goat anti-guinea pig Fab’ (1:400) (Nanoprobes, Inc., Yaphank, NY, USA) and Alexa Fluor 488-conjugated donkey anti-rabbit IgG antibodies (1:400) (Life Technologies Co., Carlsbad, CA, USA). Immunostained sections were sealed with Vectashield mounting medium (Vector Laboratories). Fluorescence signals for Alexa Fluor 488 or Alexa Fluor 594 were observed with a BX-61 fluorescence microscope (Olympus, Tokyo, Japan). After obtaining fluorescence images, some thick sections were additionally stained with TB for re-examination of morphology (Fig. 1B).

Tissue preparation and observation for serial block-face scanning electron microscopy (SBF-SEM)

Samples for SBF-SEM observations were post-fixed with osmium and stained en bloc, as described previously [30]. Briefly, mouse pancreatic tissues were prefixed with 2.5% glutaraldehyde in 0.1 M phosphate buffer (PB; pH 7.4) overnight and tissues were washed with cacodylate buffer (pH 7.4). Tissues were then treated with 2% OsO4 (Nisshin EM, Tokyo, Japan) in 0.1 M cacodylate buffer containing 0.15% K4[Fe(CN)6] (Nacalai Tesque, Kyoto, Japan) for 1 hr on ice, and 0.1% thiocarbohydrazide (Sigma-Aldrich) for 20 min and 2% OsO4 for 30 min at room temperature. Thereafter, the tissues were treated with 2% uranyl acetate at 37°C for 3 hr. Tissues were then treated with lead aspartate solution at 60°C for 30 min. The
specimens were routinely dehydrated by passing the tissue through a series of solutions with increasing ethanol concentrations, infiltrated with acetone dehydrated with a molecular sieve, a 1:1 mixture of resin and acetone, and 100% resin and then embedded in Epon 812 epoxy resin with carbon (ketjen black) at 60°C for 3 days/overnight. Following trimming of islets from mouse pancreas, samples were imaged with a Sigma™ VP (Carl Zeiss, Munich, Germany) equipped with 3View (Gatan Inc., Pleasanton, CA, USA). The serial images of SBF-SEM were handled with Fiji/ImageJ, and segmented and reconstructed to 3D images using MIB (http://mib.helsinki.fi/) and Amira software.

### III. Results

To identify compact and diffuse Langerhans islets, Epon sections of human pancreas were prepared, routinely fixed with glutaraldehyde and OsO₄, stained with TB, and observed with a light microscope (Fig. 2). The compact islets were revealed as large collections of endocrine cells having round to oval shapes (Fig. 2A, black arrowheads). Their nuclei have homogeneous chromatin patterns with nucleoli, and the cells have moderately light cytoplasm. In contrast, diffuse islets were composed of trabeculae of endocrine cells interspersed between adjacent acini (Fig. 2B, red arrowheads).

During immunohistochemical staining of the peptide hormones (insulin and glucagon) and REG1α, we noted that two pre-treatments after the removal of Epoxy resin (Fig. 1B), including antigen retrieval by autoclaving and extraction of osmium tetroxide with hydrogen peroxide, strongly increased specific staining for endocrine peptides and decreased non-specific background in the thick Epon sections (Figs. 3 and 5). The immunoreactivity of the HRP-DAB reaction was dramatically enhanced by autoclave treatment, and the effect was more prominent in insulin immunostaining (Fig. 3D and E, insets; arrows) than in glucagon immunostaining (Fig. 3F and G, insets; arrows). Immunocontrols not incubated with primary antibodies have reduced backgrounds caused by secondary antibody conjugated-HRP-DAB reaction products and osmification (Fig. 3B and C).

The use of our modified immunostaining protocol allowed clear observations of the ultrastructure of endocrine cells immunopositive for insulin, glucagon, and REG1α in serial thick and ultrathin sections in compact Langerhans islets of human pancreatic tissue (Fig. 4). Immunostaining signals for insulin in β cell granules and for glucagon in α cell granules did not colocalize in the islet cells (Fig. 4A, D–F), while patterns of immunostaining for insulin and REG1α overlapped in large parts of double-immunopositive endocrine cells (Fig. 4G–I). Immunopositive staining for insulin and glucagon was positive for most islet areas whose ultrastructures were determined in serial ultrathin sections of the same islet (Fig. 4A, D–F, J, and K). The compact islet illustrated in Fig. 4 had a higher ratio of cells positive for glucagon or insulin compared to cells from the compact islets shown in Fig. 3. Areas of α or β cells on electron microscopy images were almost completely identical to the areas immunopositive for insulin and glucagon (Fig. 4A, D–F, J, and K). These correlative observations revealed that islet cells with low and high immunoreactivity for glucagon included round-shaped granules with low and high electron density (Fig. 4P–R; blue arrows), whereas insulin-positive cells with β cell granules (Fig. 4O; red arrows) and condensing vacuoles (Fig. 4O, white arrows). Immunocontrols that were not

**Fig. 2.** Differences between compact and diffuse islets in human pancreas revealed by light microscopy observations of toluidine blue stained thick sections routinely embedded in Epon. **A:** The compact islet appears round to oval and is composed of endocrine cells surrounded with a capsule of connective tissue (black arrowheads). Blood capillaries (black arrows) separate the islet into several lobules. Endocrine cells have moderately light cytoplasm. **B:** The diffuse islet is composed of a mass of endocrine cells interspersed between adjacent exocrine acinar-like cell clusters without a clear capsule (red arrowheads) in structures that appear like acinar ducts. Bars = 20 μm.
incubated with primary antibodies have less background related to the second antibodies conjugated—Alexia 488 and 594, and in particular, because of secondary antibody cross-reactivity to native human immunoglobulins trapped in pancreas tissues around blood vessels and fixative auto-fluorescence.

Immunoreactive staining for insulin and glucagon was also clearly observed in endocrine cells of diffuse islets, while exocrine cells of adjacent glandular acini were not immunostained (Figs. 5 and 6). The immunoreactivities for REG1α and insulin showed different distributions in the same endocrine cells in serial thin sections of diffuse islets.

Fig. 3. Enhancement of immunostaining for insulin and glucagon in serial thick sections of a typical compact human pancreatic islet by autoclave treatment. A: Insulin-positive staining in a section that underwent autoclave treatment (AC). B: Immunocontrol incubated with secondary antibody without the primary antibody. C: Differential interference contrast microscope (DIC) image of the immunocontrol section. D: Weak insulin immunoreactivity in an untreated section. E: Stronger insulin immunoreactivity in a section that underwent AC—tiny granular patterns are more clearly detected throughout the cytoplasm of β cells (inset, arrows). F: Improved immunoreactivity for glucagon in the cytoplasm of cells in an untreated section. G: Clear granular pattern of immunoreactivity for glucagon in a section that underwent AC (inset, arrows). Bars = 20 μm (A–G); 10 μm (D–G, insets).
Correlative light-electron microscopy mapping of a compact islet using serial Epon sections from a human pancreatic tissue specimen. Ultrastructural observations and double-immunofluorescence staining for insulin, glucagon, and REG1α were carried out. 

**A:** Merged image of insulin and glucagon positive staining. 

**B:** Merged image of immunocontrol (red and green) exposed to two secondary antibodies without primary antibodies. 

**C:** Differential interference contrast microscope (DIC) image of immunocontrol section shown in (B). Islet cells with granular immunopositive staining for insulin (A, D, F, G, I, red) are immunopositive for REG1α (H, I, green), but not for glucagon (A, E, F, green), whereas the immunostaining patterns of insulin and REG1α largely overlap (I, yellow). Electron microscopic montages (J, K) obtained from the same field of the serial section shown in (F). The magnified image (J, K) corresponds to the white boxes in (F). The compact islet has a capsule of connective tissue (J, K, yellow asterisks). Mapping images of β cell granules (J, K, pseudo-coloured red) and α cell granules (J, K, pseudo-coloured green) manually coloured by Photoshop. Distribution patterns of insulin- (red) and glucagon-positive (green) cells (A, D–F) are clearly identified in the electron micrographs (J, K). Highly magnified electron microscopy images (O–R) correspond to the white boxes in (L) and double-immunopositive staining images (M). N: Toluidine blue staining for the same section (F) of insulin-positive cells (M, red) included β-cell granules (O, red arrows) and condensing vacuoles (O, white arrows), while glucagon-positive cells (M, green) included small numbers of round-shaped granules with low (P, blue arrows), with intermediate (Q, blue arrows) and high (R, blue arrows) electron densities. Bars = 20 μm (A–D, G); 1 μm (J–L).

Fig. 4.
Fluorescently immunostained sections were subsequently stained with TB, and islet structures were found to be well preserved following double-fluorescence immunostaining (Fig. 6G and H). Electron microscopy observations of serial ultrathin sections were performed to reveal structural details of diffuse islets in addition to identifying the hormones produced by the respective cells (Fig. 6). It was found that β cells double positive for REG1α and insulin were also the cells that exhibited zymogen-like condensing vacuoles (200–500 nm in size) and many organelles, such as mitochondria, Golgi apparatus, endoplasmic reticulum (ER), and lipofuscin granules (Fig. 6J and L, white arrows) [14]. In addition, these endocrine cell granules in contact with exocrine acinar-like cell clusters have electron-dense cores and clear halos. However, insulin and REG1α double-positive endocrine cells consisted of several granular morphologies of human islet endocrine cells. We classified the granules of human islets into four types (α-, β-, δ-, and PP-cell granules) as described previously [7, 8, 27, 34, 36], where (I) α-cell type (glucagon-secretory): electron-dense without a clear halo occasionally presenting with a grey halo (Fig. 6K, red arrowheads); (II) β-cell type (insulin secretory): granules of this type have electron-dense cores with a crystalline shape (Fig. 6K–N, blue arrowheads); (III) δ-cell type (somatostatin secretory): larger and electron-opaque (Fig. 6K, L, and N, cyan arrowheads); and (IV) PP-secretory cell type: spherical and smaller granules with a small halo (Fig. 6L, green arrowheads). Interestingly, islet endocrine cells in contact with adjacent exocrine acinar-like cell clusters (ATLANTIS) contained zymogen-like granules (Fig. 6M, yellow arrow), and cell-to-cell contacts were also detected (Fig. 6N, white arrows).

Finally, we examined the three-dimensional architecture of compact islets (tail) and diffuse islets (head) of pancreas from adult C57BL/6J mice by SBF-SEM (Fig. 7). Endocrine cells from diffuse islets were also in contact with adjacent exocrine acinar-like cell clusters (ATLANTIS) without a clear capsule (Fig. 7D–I). The morphologies of granules in endocrine cells of diffuse islets (Fig. 7F) mainly consisted of three types: (I) granules with a spherical dense core and a small halo similar to PP-cell granules (Fig. 7F, green arrowheads), (II) granules with a low electron-dense core without halo similar to δ-cell granules (Fig. 7F, cyan arrowheads), and (III) granules with a spherical or crystalline-shaped dense core with a clear halo similar to β-cell granules [35]. We also found on serial SBF-SEM images that zymogen-like granules are broadly distributed in these endocrine islet cells in contact with acinar-like cells. The zymogen-like granules have an isotropic distribution from ATLANTIS to the islet cells through direct contact with lamellar ERs in diffuse islets of the pancreatic head portion in adult normal mice derived from ventral origins (Fig. 7G–I).

IV. Discussion

In the present study, by combining etching of hydrophobic Epon with preliminary autoclaving and exposure to hydrogen peroxide, we developed a technique that allows the simultaneous analysis of cellular ultrastructure and localisation of endocrine peptides in human pancreas samples.

Combined analyses using immunohistochemical localisation of hormones and ultrastructure of endocrine cells in animal pituitary glands have been previously reported [2]. In those studies, to achieve simultaneous examination, Epon thick sections were prepared from tissues fixed with glutaraldehyde and OsO₄, and peroxidase-DAB immunostaining was used for light microscopy, while electron microscopic observations were carried out in serial ultrathin sections [2]. Conventional double fixation was useful because lipid membranes, such as the plasma membrane of cells and vesicles, are well preserved. Epon-embedded sections are frequently used for ultrastructural analyses by electron microscopy because they exhibit well-preserved tissue morphology. However, the weak tissue antigenicity of Epon-embedded sections poses a problem for immuno-
Correlative light-electron microscopy mapping of a diffuse islet using serial Epon sections from a human pancreatic tissue specimen. Ultrastructural observation and double-immunofluorescence staining for insulin, glucagon, and REG1α were carried out. Granular immunoreactivities for insulin (A, C, red) and glucagon (B, C, green) are sparse and dense respectively, while the immunostaining patterns of insulin (D, F, red) and REG1α (E, F, green) largely overlap. G: A light microscopy image of the same thick section stained with toluidine blue (TB) after microscopy observation of fluorescence immunostaining (A–C). The diffuse islet is composed of a mass of endocrine cells in contact with adjacent exocrine acinar-like cell clusters without a clear capsule (red arrowheads). H: Superimposed image of (C) and (G). I: An electron microscopy image of the black-boxed area shown in (G) obtained from a serial ultrathin section demonstrating the ultrastructural features of insulin- and glucagon-positive endocrine cells in a diffuse pancreatic islet. The diffuse islet is composed of a mass of endocrine cells interspersed between adjacent exocrine acinar-like cell clusters without a clear capsule (red arrowheads). J: An electron microscopy montage showing a pancreatic islet corresponding to the rectangle of TB staining shown in (G). Endoplasmic reticulum and Golgi apparatus are indicated by blue and red arrowheads, respectively. K: A higher magnification image of the respective boxed area in (J) illustrating an α cell containing α-cell granules (red arrowheads) in contact with a β cell containing β-cell granules (blue arrowheads) and condensing small vacuoles (cyan arrowheads). L: A higher magnification image of the respective boxed area in (J) illustrating a β cell with β-cell granules (blue arrowheads) and spherical and smaller granules with small halo (green arrowheads) in contact with an α cell containing α-cell granules (red arrowheads). M: A higher magnification image of the respective boxed area in (J) illustrating a β cell with β-cell granules (blue arrowheads) and a zymogen-like granule (yellow arrow) in cell-to-cell contact with an exocrine acinar-like cell containing zymogen-like granules. N: Interdigitation of cell membranes (white arrows) containing β-cell granules (blue arrowheads) and 200–500-nm condensing vacuoles (cyan arrowheads) between two β cells. Bars = 50 μm (A, D, G); 5 μm (I); 2 μm (J); 500 nm (K, N); 1 μm (L, M).
Serial block-face scanning electron microscopy (SBF-SEM) observations of compact and diffuse islets from pancreatic tissues of a C57BL/6J mouse. 

A: The compact islet is composed of a mass of endocrine cells with a clear capsule from the tail portion of the pancreas. 

B: \( \alpha \) cells and \( \beta \) cells localized in the corner of an islet in contact with a capsule. 

C: \( \alpha \)-cell granules (blue arrowheads) are electron dense without a core, while \( \beta \)-cell granules (red arrowheads) show angular-shaped cores with a clear halo. 

D–E: The diffuse islet is composed of a mass of endocrine cells in contact with adjacent exocrine acinar-like cell clusters (ATLANTIS) (red arrowheads) without a clear capsule (blue arrowheads). 

F: The islet endocrine cells contain three type of granules: 1) spherical smaller granules with a small halo (green arrowheads), 2) slightly electron opaque but spherical granules without a halo having a similar size to \( \alpha \)-cell granules (cyan arrowheads), and 3) granules with zymogen-like granules (yellow arrows). The ATLANTIS containing \( \beta \)-cell granules (red arrowheads). 

G: Montage picture of the islet endocrine cells and ATLANTIS in the diffuse islet (D) showing every 10 serial images of a total of 70 images at 50-nm thickness each. The ATLANTIS containing zymogen-like granules (G10th, white arrows), isotopically localized to the islet cells (G10th, blue arrows), and in direct contact with endocrine cells with lamellar endoplasmic reticuli (G10th, red arrowheads). Islet cells are partially separated from the acinar-like cell clusters with connective tissues by blood vessels (G70th, blue arrowheads). 

H: Magnified image of (G10th).

assays. There have been attempts to improve immunolabeling of epoxy sections by etching hydrophobic Epoxy resin with different alkali solutions [26], retrieving antigenicity by sodium metaperiodate [3, 33], protease treatments [18], or heating (autoclaving or microwave) thick or ultrathin-sections for immunoelectron microscopy with various salt solutions [15, 25, 37, 47, 49]. In the present study, in addition to etching the hydrophobic Epon, we utilized autoclaving and pre-treatment with hydrogen peroxide to enhance endocrine peptide immunoreactivity. It is believed that heating treatment retrieves immunoreactivity of masked antigens by exposing epitopes hidden because of cross-linking with aldehyde fixatives, whereas hydrogen peroxide treatment may increase immunoreactivity by reducing osmification of the target molecules [15, 47]. These pretreatments of Epon section are broadly applied to antibodies of immunohistochemistry not only for peptide hormones but also for several organelle markers; mitochondria, lysosome and peroxisome or membrane proteins (aquaporin-1,-2 and megalin), or soluble proteins; immunoglobulins (IgA and Ig kappa light chain), J-chain, and albumin [18, 37, 49]. Overall, we demonstrated that a combination of double fixation, embedding in Epon, and immunohistochemistry with effective pre-treatments was a very useful and robust approach for the simultaneous examination of cellular ultrastructure and antigen distribution in individual cells of human pancreas. Points to be aware of regarding to pit-fall or the limitations of this method: (i) careful select for combination of first antibodies in double fluorescent immunostaining, matching for the pretreatments conditions (heating or de-osmification), (ii) weaker DAPI staining for nucleus fluorescence staining after autoclaving.

Correlative light and electron microscopy analyses of serial thick and ultrathin sections showed intracellular organelles and membrane interdigitations near cell-cell contact areas as well as typical α or β-cell granules in individual insulin- and glucagon-positive endocrine cells located in both compact and diffuse islets (Figs. 4 and 6). Human Langerhans islets contain polygonal endocrine cells that are demarcated by intercellular structures, such as tight junctions, gap junctions, and membrane structures, including interdigitations and invaginations [32]. In diffuse Langerhans islets, we found that some endocrine cells appear to have direct cell-to-cell contacts with adjacent endocrine and exocrine acinar-like cells (Fig. 6). These results indicate that electric or metabolic coupling exists not only between adjacent endocrine cells, but also between endocrine cells and the surrounding pancreatic exocrine acinar-like cell clusters [1, 32]. We also identified insulin and REG1α double-positive cells that contained zymogen-like condensing granules in the endocrine islet cells, with several types of granules morphologically classified as β-, δ-, and PP-cell like granules (Fig. 6). Using serial imaging of SBF-SEM provides a highly spatial resolution of the ultrastructure of diffuse islets from the head portion of mouse pancreas, which has a ventral origin [30, 35]. Electron microscopic observations showed the same architecture in human diffuse islets in contact with acinar-like cells without a clear capsule. The typical diffuse endocrine islet in contact with acinar-like cells showed typical features of being rich in PP with a paucity of glucagon [8, 38]. Further, endocrine islet cells localized most of the PP-cell-like granules and zymogen-like granules directly through cell-cell contact sites with lamellar ERs, even if zymogen-like granules were excreted from the ATLANTIS. Using the correlative light and electron microscopy imaging described in the present study, additional basic and clinical studies for the precise identification of the observed granules in glucagon- and insulin-positive cells as well as the immunohistochemical detection of peptide components in human Langerhans islets for detailed clinical analyses of diabetes mellitus and chronic kidney or intestinal diseases closely related to metabolic disorders warrant further investigation [1, 4, 9, 11–14, 20, 22, 27, 49].

Interestingly, recently developed super-resolution imaging enables a detailed analysis distribution of biological molecules at an even higher resolution (e.g., a lateral resolution of 20–50 nm) by stochastic optical reconstruction microscopy when it is combined with new light microscopy technologies for nano-level analyses, an approach which may be applied to chemically fixed and Epon-embedded specimens [19, 39, 45]. In combination with immunohistochemistry and in situ hybridization in Epon sections, the correlative microscopy observation method would be a more powerful approach capable of revealing human islet regeneration under genomic and transcriptome control such as SSTR expression in β cells from human islets [7, 8, 25].
V. Conflicts of Interest

The authors declare that there are no conflicts of interest.
