Spider silks combine a significant number of desirable characteristics in one material, including large tensile strength and strain at breaking, biocompatibility, and the possibility of tailoring their properties. Major ampullate gland silk (MAS) is the most studied silk and their properties are explained by a double lattice of hydrogen bonds and elastomeric protein chains linked to polyalanine \(\beta\)-nanocrystals. However, many basic details regarding the relationship between composition, microstructure and properties in silks are still lacking. Here we show that this relationship can be traced in flagelliform silk (Flag) spun by Argiope trifasciata spiders after identifying a phase consisting of polyglycine II nanocrystals. The presence of this phase is consistent with the dominant presence of the –GGX– and –GPG– motifs in its sequence. In contrast to the passive role assigned to polyalanine nanocrystals in MAS, polyglycine II nanocrystals can undergo growing/collapse processes that contribute to increase toughness and justify the ability of Flag to supercontract.

Flagelliform (Flag) silk and major ampullate gland silk (MAS) are the two most studied silks among those spun by spiders and, although their biological functions differ, were found to share the conserved motifs –GPG– and –GGX–1. MAS is widely considered as the reference spider silk due not only to its unrivalled combination of tensile strength and strain at breaking2, but also to the development of techniques that allow access to large amounts of material3. Its tensile properties are explained by a double lattice model4 consisting of a mesh of hydrogen bonds established between the protein residues, superimposed to a mesh of elastomeric protein chains5 anchored to protein nanocrystals6. This model accounts qualitatively for the most remarkable properties of spider silks, including the ability to supercontract7, and fits nicely to the protein sequence8. In this regard, it was found that one of the main motifs of sequence present in MAS spidroin, the polyalanine runs (–An–), pile up to form \(\beta\)-nanocrystals. The exact role of the other three conserved motifs –GA– and, especially, of those shared with Flag –GGX– and –GPG– is much less clear.

Flagelliform (Flag) silk is the silk used by orb-web spiders in the core of the sticky viscid line that makes up the spiral of the web. Flag represents another rich opportunity to study the relationship between composition, microstructure and behaviour in silks, since it also shows remarkable tensile properties9,10 and the ability to supercontract11, but its sequence differs significantly from that of MAS. In this regard, it was found that one of the main motifs of sequence present in MAS spidroin, the polyalanine runs (–An–), pile up to form \(\beta\)-nanocrystals. The exact role of the other three conserved motifs –GA– and, especially, of those shared with Flag –GGX– and –GPG– is much less clear.

Results

Figure 1a shows the true stress-true strain curves of Flag fibers after removal of the viscous coating, and being subsequently subjected to wet stretching processes defined by different values of the alignment parameter, \(\alpha\)13. At least four samples were tested for each value of the alignment parameter and their main mechanical parameters

Flag fibers with reproducible and predictable mechanical properties, and by the small scattering of the mechanical parameters (see Table 1), it is demonstrated that this procedure allows obtaining a maximum supercontracted fibers, and represents the ground state that is reached after maximally supercontracted fibers. The existence of a ground state that is reached after maximum supercontraction allows extrapolating this process to Flag silk, in which the dynamics of polyglycine II nanocrystals are observed to vary and these variations are found to depend on the configuration and stretching of the protein chains. In this context, access to the diffraction patterns of fibers with different values of $\alpha$ allows determining their dynamics during stretching or, conversely, supercontraction. No change in the unit cell is observed with varying values of $\alpha$. However, crystallinity, and the size and orientation of the nanocrystals appear to be strongly influenced by this value (Figure 3). In this regard, the nanocrystals are shown to align with the macroscopic axis of the fiber (Figure 3a), and crystallinity increases steadily with increasing values of $\alpha$ ($\chi = 5\%$ at $\alpha = 0$ and $\chi = 10\%$ at $\alpha = 0.9$) (Figure 3b), as previously described in MAS fibers. In contrast to the constancy shown by the dimensions of MAS nanocrystallites with increasing $\alpha$, the size of Flag nanocrystals is observed to vary and these variations are found to depend on the crystallographic direction. Thus, it is found that the length $L_{(100)}$ decreases with increasing $\alpha$, meanwhile the length $L_{(002)}$ (approximately parallel to the macroscopic axis of the fiber) shows the opposite behavior (Figure 3c).

AFM analysis of maximally supercontracted Flag fibers ($\alpha = 0$) reveals a nanoglobular microstructure comparable to that found in other natural and artificial silk fibers (Figure 4). The nanoglobules were approximated by ellipses with sizes $11 \pm 3$ nm (major axis, with a maximum value of 20 nm) and $8 \pm 2$ nm (minor axis).

### Discussion

Combination of the mechanical and microstructural data presented above allows establishing a coherent picture of the behaviour of Flag silk, in which the dynamics of polyglycine II nanocrystals are assigned a leading role. Thus, the overall true stress–true strain curves presented in Figure 1 are compatible with the assumption of three regimes in the mechanical behaviour of silks: initial deformation of hydrogen bonds, yielding of the protein chains from their initial configuration and stretching of the protein chains. In this context,
the increase in polyglycine II crystallinity would be the result of conformational changes induced in the proteins during the stretching step.

Consistently with this model, it is found that crystallinity increases reversibly during the stretching of the fiber from the ground (i.e. maximum supercontracted) state due to the increase of the nanocrystal size along the direction parallel to the macroscopic axis of the fiber. This process can be reverted by supercontraction which, in turn, is shown to consist of the partial collapse of the nanocrystals. All these changes can be accounted for if it is assumed that stretching leads to a molecular reorganization of spatially close protein chains at the ends of polyglycine II nanocrystals. In this regard, fibers with larger values of α are shown to attain lower values of strain at breaking, since the conformational changes of the proteins are limited compared with those of fibers with lower values of α. With respect to its influence on the tensile behaviour, this mechanism of nanocrystal formation allows dissipating mechanical energy and, consequently, should represent a significant contribution to toughness.

The parallels and differences observed between Flag and MAS immediately suggest the question of whether these features might represent general design principles in spider silks. Although not direct evidence of the presence of polyglycine II nanocrystals in MAS is presented in this work, several indirect facts indicate that this might be the case.

Comparison of the tensile properties of Flag and MAS show a striking resemblance between the stress-strain curves of both materials at low values of α (Figure 1b). Significant differences are observed at increasing values of α, since the tensile strength of Flag silk does not increase with α, leading to an overall decrease in its work to fracture. Both silks also differ in the curvature of the stress-strain curves, which changes from convex to concave in MAS at large values of α, but remains convex in Flag independently of α, although this difference could be related with the larger values of α found in MAS, up to α = 1.44.

The improved behavior of MAS at large values of α could be related with the presence of the β-nanocrystals. Previous studies have shown that the crystalline unit cell and the size of the β-nanocrystals does not change during either stretching or supercontraction. However, the orientation of the nanocrystals with respect to the axis of the fiber and the crystalline fraction increase during stretching. Supporting the importance of β-nanocrystals for the tensile behaviour at large strains, it was found by simulation that the length of the polyalanine runs in the sequence are optimized for the formation of β-nanocrystals, whose size, in turn, is optimized to promote a redistribution of stresses in the material.

The combined effect of β- and (presumably) polyglycine II nanocrystals in MAS could explain the change from convex to concave curvature of the stress-strain curves at high values of α. Concave (convex) curvature of a stress-strain curve is usually labelled as enthalpic (entropic) behaviour and indicates that variations in the intensity of the interactions (conformational variations) are responsible for the performance of the material. The formation of polyglycine II nanocrystals in MAS would justify this transition since, after the extensive formation of the nanocrystals at large values of α, further stretching would imply the deformation of the nanocrystals, and not additional conformational changes in the chains.

Evidently, it is necessary to assess the question of whether the results found in Flag can be extrapolated to MAS. The presence of a second ordered phase in MAS that differed from the β-nanocrystals had been suggested previously, and its presence at the ends of the polyalanine nanocrystals has been established by different microstructural techniques. Most studies have extrapolated the β-pleated microstructure of the underlying polyalanine nanocrystals to the second ordered phase, but our present study suggests that the possibility of finding polyglycine II structures formed at the end of the β-nanocrystals should be considered. In addition, the XRD data presented in this work can justify the origin of the difficulty of identifying polyglycine II nanocrystals in MAS. Thus, it is found that the most intense reflection arising from polyglycine II nanocrystals corresponding to (100) overlaps with the much more intense reflections (020) and (210) arising from the polyalanine β-nanocrystals. There is, however, at least one report on MAS silk in which a diffuse scattering ring with a Q close to that of the (210) reflection is observed, that is particularly strong along the polar direction.
Furthermore, there are three indirect experimental evidences that substantiate the presence of polyglycine II nanocrystals in both Flag and MAS. (1) Comparison of the Flag and MAS sequences shows that both silks share the polyglycine II nanocrystal-forming motifs. This fact is also consistent with the simultaneous evolutionary occurrence of supercontraction and the –GGX– and –GPG– motifs\(^3\). In this regard, the analysis of recombinant Flag silk including the spacer region besides the glycine-rich motifs\(^3\) suggests that the spacer might play a role in facilitating the alignment of the other two motifs.

Figure 3 | Variation of the nanocrystal parameters with different values of \(\alpha\). (a) Orientation of the nanocrystals as measured from the FWHM of the gaussian used to fit the azimuthal profile of the equatorial Bragg peak (100). Corresponding values in MAS are included to facilitate comparison. Error bars represent standard error. (b) Variation of crystallinity as measured by (i) \(X_R\), ratio between the intensity of the (100) peak and the total intensity of a nearby section, and (ii) \(\chi\), ratio between the intensity of Bragg peaks and total intensity\(^2\). Data corresponding to MAS are shown for comparison. (c) Variation of the size of the nanocrystals in Flag along two perpendicular directions, (100) and (003), as calculated from the Scherrer’s equation.

Figure 4 | SEM and AFM characterization of flagelliform silk. (a) Two representative SEM micrographs used for computing the cross-sectional area of flagelliform fibers. The two individual filaments (each filament known as a brin) that make up the fiber (bave) are clearly identified. (b) AFM image of a longitudinal section of a Flag fiber subjected to maximum supercontraction (MS, \(\alpha = 0\)). The macroscopic axis of the fiber lies along the horizontal direction. Nanoglobules are approximated by ellipses and the histogram shows the distribution of sizes along the major and minor axes.

Furthermore, there are three indirect experimental evidences that substantiate the presence of polyglycine II nanocrystals in both Flag and MAS. (1) Comparison of the Flag and MAS sequences shows that both silks share the polyglycine II nanocrystal-forming motifs. This fact is also consistent with the simultaneous evolutionary occurrence of supercontraction and the –GGX– and –GPG– motifs\(^3\). In this regard, the analysis of recombinant Flag silk including the spacer region besides the glycine-rich motifs\(^3\) suggests that the spacer might play a role in facilitating the alignment of the other two motifs.
However, the properties of recombinant Flag fibers are still below from those of the natural material, so that extrapolating conclusions from recombinant to natural Flag fibers should be taken cautiously. (2) When the increase of crystallinity with $\tau$ is analysed (Figure 3b), it is found that both silks present the same slope of the crystallinity vs. $\tau$ curves, except for the presence of an initial offset in MAS15. This observation could be explained in part by the formation of the polyglycine II crystals in MAS, after completing the initial rotation of the polyalanine $\beta$-nanocrystals16. (3) Finally, the size of the nanoglobules observed by AFM was correlated with the longest crystal-forming fragments in silkworm silk17 and minor ampullate gland silk17. This correlation failed in MAS if the longest polyalanine fragments were considered, but combination of sequential polyalanine fragments ($\Delta L_{\alpha}$ – corresponds to 3.5 nm if $\beta$-pleated conformation is assumed) and various –GGX– or –GPG– (approx. 0.65 nm each if polyglycine II conformation is assumed) would yield values close to the experimental size of 10–14 nm.

Methods

Flagelliform fibers were obtained from webs built by Argiope trifasciata spiders and the coating (aggregate silk gland secrections) on the samples was eliminated by centrifugation18. The supercontraction procedure of cleaned Flag fibers was based on that used for MAS17. A novel procedure was developed for equalizing and adjusting the contrast and the brightness of the micrographs, was performed with WSxm program (Nanotec Electronica, Spain)19, No filter was used to improve the quality of the images or to highlight their details.

AFM analysis was performed on longitudinal sections of fibers previously embedded in Spurr’s resin20. The longitudinal sections were obtained by ultramicrotomy with a diamond blade. The AFM images were recorded in a Cervantes AFM system (Nanotec Electronica, Spain) using Olympus OMCL RC800PSA cantilevers, and the highest resolution was obtained with the stiffest tip (nominal stiffness 0.76 N/ m). AFM images were recorded in the dynamic mode in the repulsive regime of the force-distance curve21. The processing of the AFM images, consisting of simply equalizing and adjusting the contrast and the brightness of the micrographs, was performed with WSxm program (Nanotec Electronica, Spain)29. No filter was used to improve the quality of the images or to highlight their details.
