In this talk, I demonstrate that the proposed Electron-Ion Collider (EIC) will be an ideal and unique future facility to address many overarching questions about QCD and strong interaction physics at one place. The EIC will be the world’s first polarized electron-proton (and light ion), as well as the first electron-nucleus collider at flexible collision energies. With its high luminosity and beam polarization, the EIC distinguishes itself from HERA and the other fixed target electron-hadron facilities around the world. The EIC is capable of taking us to the next QCD frontier to explore the glue that binds us all.

Keywords: Electron-Ion Collider, QCD, hadron structure, gluon saturation.

PACS numbers:

1. Introduction

Understanding the evolution of our universe from its origin (the Big Bang) to its current state, and the fundamental structure of all matters within it, is one of the most central goals of human scientific endeavor. The evolution is intimately tied to the properties of and the dynamics between fundamental particles that existed in each of its phases. The structure of matter encodes all the history and secrets of the evolution waiting for us to explore.

It is the discovery of the atomic structure and the nucleus by the Rutherford experiment over 100 years ago that led to the discovery of quantum mechanics and the quantum world, which forever changed our view of the universe that we are living in. It is the modern “Rutherford” experiment, scattering between an electron and a proton, performed at Stanford Linear Accelerator Center (SLAC) in the sixties that discovered quarks, the fundamental constituents of the proton, which led to the

discovery of Quantum Chromo-Dynamics (QCD) — the theory of strong interacting color charges that is responsible for confining colored quarks into all known color neutral hadrons by the exchange of gluons. In contrast to the quantum electromagnetism, where the force carrying photons are electrically neutral, the force carrying gluons carry the color charge causing them to interact among themselves, which is the defining property of QCD responsible for the confinement of color and the asymptotic freedom of color force, two remarkable, while seemingly contradicted, properties of QCD. It is the HERA at DESY, Germany — the only electron-proton collider ever built in the world that observed the dramatic rise of the probability to find a gluon carrying a small fraction \( x \) of the momentum of colliding proton, which led to a tremendous effort in both theory and experiment in recent years to search for a novel phenomenon of gluon saturation — an expected consequence of strong gluon fields and the non-linear QCD dynamics. Knowing the properties and underlying QCD dynamics of matter at high gluon density is critically important for understanding the dynamical origin of the newly discovered quark-gluon plasma (QGP) in relativistic heavy ions collisions. Without gluons there would be no protons, no neutrons, and no atomic nuclei. All matter as we know of would not exist. The glue binds us all. Understanding the properties of the glue and its role in determining the internal structure and interactions of nucleons and nuclei, as well as their emergence from colored quarks and gluons, as dictated by QCD, is a fundamental and compelling goal of nuclear science.

In this talk, I briefly review the proposed Electron-Ion Collider (EIC), and highlight its science case for building it in the United States. Much of the physics presented here are fully documented in the EIC White Paper\(^1\), put together by a writing committee, appointed jointly by the managements of Brookhaven National Laboratory (BNL) and Jefferson Laboratory (JLab), with many valuable suggestions and comments from the broad nuclear physics community.

2. Electron Ion Collider

Since its introduction over forty years ago, QCD has been extremely successful in interpreting data from all high energy \( e^+ e^- \), lepton-hadron and hadron-hadron collisions with momentum transfer(s) \( \gg \Lambda_{\text{QCD}} \sim 1/\text{fm} \); and \emph{ab initio} lattice QCD calculations have provided an impressive description of mass spectrum of all known hadron.\(^2\) While no one questions the validity of QCD today as a fundamental theory of strong interactions in the Standard Model, our understanding of QCD remains incomplete. We know very little of the quark-gluon structure of hadrons and the emergence of hadrons from quarks and gluons, which are closely connected to the defining property of QCD — the color confinement — one of the Millennium Prize Problems stated by the Clay Mathematics Institute in 2000.

The EIC with its unique capability to collide polarized electrons with polarized protons and light ions at unprecedented luminosity, and with heavy nuclei at high energy, will be the first precision microscope able to explore how gluons bind quarks
to form protons and heavier atomic nuclei. By precisely imaging gluons and sea quarks inside the proton and nuclei, the EIC will address some of the deepest and the most intellectually pressing questions in QCD:

- **How are the sea quarks and gluons, and their spins, distributed in space and momentum inside the nucleon?** How are these quark and gluon distributions correlated with overall nucleon properties, such as spin direction? What is the role of the orbital motion of sea quarks and gluons in building the nucleon spin?

- **Where does the saturation of gluon densities set in?** Is there a simple boundary that separates this region from that of more dilute quark-gluon matter? If so, how do the distributions of quarks and gluons change as one crosses the boundary? Does this saturation produce matter of universal properties in the nucleon and all nuclei viewed at nearly the speed of light?

- **How does the nuclear environment affect the distribution of quarks and gluons and their interactions in nuclei?** How does the transverse spatial distribution of gluons compare to that in the nucleon? How does nuclear matter respond to a fast moving color charge passing through it? Is this response different for light and heavy quarks?

Answers to these questions are essential for understanding the nature of the visible world. A full understanding of QCD, in a regime relevant to the structure and properties of hadrons and nuclei, demands precision measurements at the EIC to explore them in their full complexity. Theoretical advances over the past decade have provided quantitative links between such measurements and the above questions that physicists are trying to answer.

The EIC will distinguish itself from all past, current, and contemplated facilities around the world by being at the intensity frontier with a versatile range of kinematics and beam polarizations, as well as beam species, allowing the above questions to be tackled at one facility. The EIC machine designs are aimed at achieving:

- Highly polarized ($\sim 70\%$) electron and nucleon beams
- Ion beams from deuteron to the heaviest nuclei (uranium or lead)
- Variable collision energies, $\sqrt{s} \sim 20 - \sim 100$ GeV, upgradable to $\sim 140$ GeV
- High collision luminosity $\sim 10^{33-34}$ cm$^{-2}$s$^{-1}$
- Possibilities of having more than one interaction region

Achieving these challenging technical improvements in a single facility will extend U.S. leadership in accelerator science and in nuclear science.

### 3. Scientific highlights and golden measurements at the EIC

The EIC with its high energy, high luminosity, polarization, and various ion beams will unite and extend the scientific programs at CEBAF and RHIC in dramatic and fundamentally important ways.
3.1. Nucleon spin

Several decades of experiments on deep inelastic scattering (DIS) of electron or muon beams off nucleons have taught us how quarks and gluons (collectively called partons) share the momentum of a fast-moving nucleon. They have not, however, completely resolved the question of how partons share the nucleon’s spin and build up other nucleon intrinsic properties, such as its mass and magnetic moment. Following an intensive and worldwide experimental program over the past two decades, including recent measurements at RHIC, along with state-of-the-art QCD global analyses, we learned that the spin of quarks and antiquarks is only responsible for $\sim 30\%$ of the proton spin, while the contribution from the gluons’ spin is about 20-30\% from the $x$-range explored so far. EIC would greatly increase the kinematic coverage in $x$ and $Q^2$, as shown in Fig. 1(Left), and hence, reduce the uncertainty of gluonic contribution to the proton’s spin in a very dramatic way, as shown by red and yellow bands in Fig. 1(Right). Clearly, the EIC will make a huge impact on our knowledge of these quantities, unmatched by any other existing or anticipated facility. The reduced uncertainties would definitively resolve the question of whether parton spin preferences alone can account for the overall proton spin, or whether additional contributions are needed from the orbital angular momentum of partons in the nucleon.

3.2. Confined motion of quarks and gluons inside the nucleon

Semi-inclusive DIS (SIDIS) measurements have two naturally different momentum scales: the large momentum transfer from the electron beam that ensures the spatial resolution of the probe, and the momentum of the produced hadrons perpendicular to the direction of the momentum transfer that prefers a small value sensitive to the motion of confined partons. Remarkable theoretical advances over the past decade have led to a rigorous framework where information on the confined motion of the partons inside a fast-moving nucleon is matched to transverse-momentum
dependent parton distributions (TMDs). TMDs allow us to investigate the full three-dimensional quark-gluon dynamics inside the proton, about which very little is known to date. In Fig. 2 (Left), the probability distribution (the color code) to find the up quarks inside a proton moving in the z-direction (out of the page) with its spin polarized in the y-direction is plotted as a function of quark transverse-momentum. The anisotropy in transverse momentum is induced by the correlation between the proton’s spin direction and the motion of its quarks and gluons. While the figure is based on a preliminary extraction of this distribution from current experimental data, nothing is known about the spin and momentum correlations of the gluons and sea quarks. The EIC will be crucial to initiate and realize such a program, and it will dramatically advance our knowledge of the motion of confined gluons and sea quarks in ways not achievable at any existing or proposed facility.

Fig. 2. Left: The transverse-momentum distribution of an up quark with longitudinal momentum fraction $x = 0.1$ in a transversely polarized proton moving in the z-direction, while polarized in the y-direction. The color code indicates the probability of finding the up quarks. Right: The projected precision of the transverse spatial distribution of gluons as obtained from the cross-section of exclusive $J/\psi$ production at the EIC.

### 3.3. Spatial Imaging of quarks and gluons inside the nucleon

By choosing particular final states in electron+proton scattering without breaking the proton, the EIC with its unprecedented luminosity and detector coverage will be able to create detailed spatial images of quarks and gluons in the colliding proton. These tomographic images obtained from cross-sections and polarization asymmetries for exclusive processes are encoded in generalized parton distributions (GPDs), and are complementary to the one obtained from the TMDs of quarks and gluons, revealing aspects of proton structure that are intimately connected with the dynamics of QCD at large distances. In Fig. 2 (Right), the spatial distribution of gluons, as measured in the exclusive process: electron + proton → electron + proton + $J/\psi$, is plotted as a function of $b_T$, the transverse position of the gluons. Such measurements would reveal aspects of proton structure that are intimately connected with QCD dynamics at large distances.
3.4. QCD matter at an extreme gluon density

When fast moving hadrons are probed by a high resolution local probe, the low-momentum gluons contained in their wave functions become experimentally accessible. The large soft-gluon density at small-\( x \), especially in a large nucleus, enables the gluon-gluon recombination to limit the density growth. Such a QCD self-regulation mechanism necessarily generates a dynamic scale from the interaction of high density massless gluons, known as the saturation scale, \( Q_s \), at which gluon splitting and recombination reach a balance. At this scale, the density of gluons is expected to saturate, producing new and universal properties of hadronic matter. The saturation scale \( Q_s \) separates the condensed and saturated soft gluonic matter from the dilute, but confined, quarks and gluons in a hadron, as shown in Fig. 3 (Left). Such universal cold gluon matter is an emergent phenomenon of QCD dynamics and of highly scientific interest and curiosity. With its wide kinematic reach, the EIC will be the first experimental facility capable of exploring the internal three-dimensional sea quark and gluon structure of a fast-moving nucleus, and the transition from a dilute to a dense gluon density to provide access to a so far unconfirmed regime of matter where abundant gluons dominate its behavior.

The existence of such saturated soft gluon matter is a direct consequence of gluon self-interactions in QCD. With many more soft gluons at the same impact parameters in a large nucleus, enhanced by \( A^{1/3} \) with the atomic weight \( A \), than that in a proton, the gluon saturation is much easier to be reached in \( e + A \) than \( e + p \) collisions. By measuring the ratio of diffractive over total cross-section for DIS on gold normalized to DIS on proton for different values of mass squared of hadrons produced in the collisions with and without saturation.

The EIC would provide the first unambiguous evidence for the novel QCD matter of saturated gluons. The EIC is poised to explore with precision the strong gluon field of collective dynamics of saturated gluons at high energies. Furthermore, knowing the
properties of this matter and its underlying QCD dynamics is critically important for understanding the dynamical origin of the creation of the QGP from colliding two relativistic heavy ions.

3.5. **Quark and gluon landscape in a nucleus**

The EMC experiment at CERN and experiments in the following two decades clearly revealed that the distribution of quarks in a fast-moving nucleus is not a simple superposition of their distributions within nucleons, as shown in Fig. 4. With its much wider kinematic reach in both $x$ and $Q^2$, the EIC could measure the suppression of the structure functions to a much lower value of $x$, approaching the region of gluon saturation. In addition, the EIC could for the first time reliably quantify the nuclear gluon distribution over a wide range of momentum fraction $x$. If the nuclear

![Fig. 4. Left: The ratio of nuclear over nucleon $F_2$ structure function as a function of Bjorken $x$, with data from existing fixed target DIS experiments at $Q^2 > 1$ GeV$^2$, along with the QCD global fit from EPS09. Also shown is the expected kinematic coverage of the inclusive measurements at the EIC. The purple error band is the expected systematic uncertainty at the EIC assuming a 2% (a total of 4%) systematic error, while the statistical uncertainty is expected to be much smaller. Right: The ratio of the semi-inclusive cross-section for producing a pion (red) composed of light quarks, and a $D^0$ meson (blue) composed of heavy quarks in $e+$lead collisions to $e+$deuteron collisions, plotted as a function of $z$, the ratio of the momentum carried by the produced hadron to that of the exchange virtual photon.](image-url)

...effect on the DIS cross section, as shown in Fig. 4, is mainly due to the abundance of nucleons at the same impact parameter of the nucleus (proportional to $A^{1/3}$), while the elementary scattering is still relatively weak, one would expect the ratio of nuclear over nucleon structure functions to saturate when $x$ goes below 0.01, as shown, for example, by the upper line of the blue area extrapolated from the current data. On the other hand, if the soft gluons are a property of the whole nucleus and the coherence is strong, one would expect the ratio of the nuclear to nucleon structure function to fall continuously as $x$ decreases, as sketched by the lower line of the blue band, and eventually, reach a constant when both nuclear and nucleon...
structure functions are in the saturation region. From the size of the purple error band in Fig. 4, which is the expected systematic uncertainty at the EIC (while the statistical uncertainty is expected to be much smaller), the EIC could easily distinguish these two extreme possibilities to explore the nature of sea quarks and soft gluons in a nuclear environment.

3.6. Hadronization and energy loss

The exact mechanism of colored partons passing through colored media, both cold nuclei and hot matter (the QGP), and the emergence of hadrons from the colored partons is not understood. A nucleus at the EIC would provide a femtometer filter to help determine the correct mechanism by which colored partons interact and hadronize in nuclear matter. By measuring pion and $D^0$ meson production in both $e + p$ and $e + A$ collisions, the EIC would provide the first measurement of the quark mass dependence of the response of nuclear matter to a fast moving quark. The dramatic difference between them, shown in Fig. 4 (Right), would be easily discernable at the EIC. The color bands reflect the limitation of our knowledge on hadronization – the emergence of a pion from a colored quark. Enabling all such studies in one place, the EIC will be a true “QCD Laboratory”, unique of its kind in the world.

4. Summary and outlook

The EIC is a ultimate machine to discover and explore the three-dimensional sea quark and gluon structure of nucleons and nuclei, to search for hints and clues of the color confinement, to study the color neutralization, and to probe the existence of the saturated gluon matter and to explore it in detail. The EIC promises to propel both CEBAF and RHIC physics programs to the next QCD frontier, and thus, will enable the US to continue its leadership role in nuclear science research through its quest for understanding the QCD and gluon-dominated nature of visible matter in the universe.

Acknowledgments

I thank all members of the EIC White Paper Writing Committee, especially, my co-editors, Abhay Deshpande and Zein-Eddine Meziani, for helpful discussions and the collaboration. This work was supported in part by the U. S. Department of Energy under Contract No. DE-AC02-98CH10886, and the National Science Foundation under Grants No. PHY-0969739 and No. PHY-1316617.
