In a class of frustrated magnets known as spin ice, magnetic monopoles emerge as classical defects and interact via the magnetic Coulomb law. With quantum-mechanical interactions, these magnetic charges are carried by fractionalized bosonic quasi-particles, spinons, which can undergo Bose–Einstein condensation through a first-order transition via the Higgs mechanism. Here, we report evidence of a Higgs transition from a magnetic Coulomb liquid to a ferromagnet in single-crystal Yb$_2$Ti$_2$O$_7$. Polarized neutron scattering experiments show that the diffuse [111]-rod scattering and pinch-point features, which develop on cooling are suddenly suppressed below $T_C$~0.21 K, where magnetic Bragg peaks and a full depolarization of the neutron spins are observed with thermal hysteresis, indicating a first-order ferromagnetic transition. Our results are explained on the basis of a quantum spin-ice model, whose high-temperature phase is effectively described as a magnetic Coulomb liquid, whereas the ground state shows a nearly collinear ferromagnetism with gapped spin excitations.
Emergent magnetic monopoles\(^1\) have recently been identified in many condensed-matter systems\(^2\)–\(^5\). In particular, recent experiments\(^6\)–\(^9\) have shown that the low-temperature state of dipolar spin-ice materials\(^10\)–\(^11\), \(\text{Ho}_2\text{Ti}_2\text{O}_7\) and \(\text{DY}_2\text{Ti}_2\text{O}_7\), can be effectively described as a classical magnetic Coulomb phase, which hosts these emergent magnetic monopoles obeying the magnetic Coulomb law\(^2\)–\(^3\). Theoretically, this has been understood from a classical model where (111) Ising moments, that is, pseudospin-1/2 moments, interact mainly through a magnetic dipolar interaction\(^10\). This classical Coulomb phase is characterized by dipolar spin correlations with a power-law decay\(^2\)–\(^3\).

Quantum variants of spin ice\(^13\)–\(^16\) have also been found in the magnetic pyrochlore oxides \(\text{RE}_2\text{TM}_2\text{O}_7\) (ref. \(^17\)) with the rare-earth (RE) ions \(\text{Yb}\) (refs \(18\)–\(25\)) and \(\text{Pr}\) (refs \(15,16,26,27\)) and transition-metal (TM) ions such as \(\text{Ti}\) and \(\text{Ir}\), or \(\text{Sn}\). In this quantum version of spin ice, the magnetic monopole charges are expected to be carried by fractionalized pseudospin-1/2 quantum-mechanical quasi-particles, spinons, that acquire kinetic energy by hopping via a pseudospin-flip exchange interaction, if they remain deconfined with an energy gap\(^2\)–\(^3\). Thus, these systems provide a unique playground to study the intriguing quantum dynamics of monopol spinons. Quantum spin ice actually harbours the analogous quantum electrodynamics, where the ‘electric field’ and ‘electric charge’ describe the Ising magnetic moment and the associated monopole charge, respectively\(^7\)–\(^12\). In particular, \(\text{Yb}_2\text{Ti}_2\text{O}_7\) provides a prototypical system described by an effective pseudospin-1/2 quantum spin-ice model\(^15\)–\(^20\), showing strong transverse quantum fluctuations of magnetic dipoles as a result of the following three characteristics: First, the crystal field structure of the \(\text{Yb}^{3+}\) ion is characterized by a ground-state Kramers doublet well-separated from the first excited doublet\(^2\)–\(^2\). Second, the Curie–Weiss temperature is weakly ferromagnetic with \(\Theta_{\text{CW}}\approx -0.53\text{ K}\) (ref. \(24\)) as in dipolar spin ice\(^13\). Third, the ground state has planar components, \(g^2=1.77\) (ref. \(22\)), enhancing the contributions to the magnetic neutron scattering cross-sections from planar fluctuations.

An early specific-heat measurement on a powder sample of \(\text{Yb}_2\text{Ti}_2\text{O}_7\) revealed a sharp singularity at 0.21 K, signalling a first-order phase transition\(^2\)–\(^3\). A previous neutron scattering experiment, on a single crystal in which we have subsequently shown that the specific-heat anomaly is reproduced (Supplementary Fig. S1), found an almost collinear ferromagnetic structure with an ordered \(\text{Yb}^{3+}\) magnetic moment of 1.1\(\mu\)\(B\), a uniform magnetization along \((100)\) and a slow relaxation of the spins over times of the order of 2 h well below \(T_c\approx0.21\text{ K}\) (ref. \(24\)). These results may indicate the formation of an energy gap in the spin excitations below a first-order phase transition to the ferromagnetic state. We have shown from specific-heat measurements (Supplementary Fig. S1) and extended X-ray absorption fine structure (EXAFS) experiments (Supplementary Fig. S2) on three different single crystals (see Methods), that the long-range ferromagnetic order in \(\text{Yb}_2\text{Ti}_2\text{O}_7\) is quite sensitive to \(\text{Yb}\) deficiency. In particular, our analysis indicates that as the \(\text{Yb}\) deficiency increases, the specific-heat anomaly becomes significantly broader and the sharp anomaly is lost (Supplementary Fig. S1). This provides an understanding of the experimental results reported for different single-crystal and polycrystalline samples of \(\text{Yb}_2\text{Ti}_2\text{O}_7\), which suggest magnetic correlations remain short-range and dynamic even below 0.21 K (refs \(18,23,25\)). The variation in the experimental findings on different samples suggests the proximity of this material to a quantum phase transition between a quantum magnetic Coulomb phase (U(1) spin liquid)\(^2\) and a magnetically ordered phase (Fig. 1a). The magnetic ordering in this case can be understood as a Bose–Einstein condensation of monopolar spinons within the Higgs mechanism\(^29\)–\(^30\), which gaps out all the soft spin excitations and takes a first-order character\(^28\)–\(^30\), as in the case of normal-to-superconductor transitions\(^31\). This first-order phase transition at zero temperature should extend to finite temperatures\(^32\). Suppose that the transition temperature is much lower than an energy \(J_2\) required for thermally and dynamically exciting monopolar spinons and that the high-temperature phase does not suffer from a static and thus non-uniform proliferation of monopole charges that causes a spontaneous symmetry breaking. Then, the high-temperature phase may be described as a magnetic Coulomb liquid at temperatures lower than \(J_2\), as in dipolar spin ice. Furthermore, the low-temperature phase transition can be effectively described as a Higgs transition of magnetic monopoles, like that of electric monopoles in the classical case\(^33\). The minimal requirement for the identification of this Higgs transition of magnetic monopoles is the observation of a first-order phase transition separating a high-temperature Coulomb phase that may be characterized by pinch-point features\(^7\)–\(^12\),\(^13\) and a low-temperature magnetically ordered phase that exhibits finite planar components of pseudospins and gapped spin excitations.

In this article we report evidence of a Higgs transition from a magnetic Coulomb liquid to a ferromagnet, from data that were collected using low-temperature polarized neutron scattering experiments on a single crystal of \(\text{Yb}_2\text{Ti}_2\text{O}_7\). We observe that well below \(T_C=0.21\text{ K}\) the incident polarized neutron beam is completely depolarized. This is ascribed to the formation of macroscopic ferromagnetic domains. The first-order nature of the phase transition is revealed via the observation of a thermal hysteresis around \(T_C\). A nearly collinear ferromagnetic structure consistent with previous neutron scattering experiments on the same single crystal\(^24\) is identified theoretically using an effective pseudospin-1/2 quantum spin-ice model on a microscopic basis\(^16\),\(^15\),\(^12\). The model also reproduces our polarization-dependent magnetic neutron scattering data above \(T_C\), showing dipolar spin correlations with a remnant of a pinch-point singularity as a signature of an unusual finite-temperature
paramagnetic phase, which in practice can be described as a classical magnetic Coulomb liquid.\textsuperscript{7,8,12,13}

**Results**

**Diffuse scattering and pinch-point features above** $T_C$. Figure 2a shows the experimental magnetic diffuse neutron scattering cross-sections collected at 0.3 K in the energy-integrated diffraction mode with an integration over the energy transfer up to 3.64 meV. The background has been subtracted (Supplementary Methods). Here, the incident neutron spins were polarized along the $Z$ direction, perpendicular to the $(h,h,l)$ plane, allowing us to probe the scattering intensities in the spin-flip (SF) and the non-SF (NSF) channels as well as for the sum of these two channels. A broad intensity from (000) through (111) to (222) is identified in the sum (Fig. 2a, right), as previously reported in unpolarized neutron scattering experiments.\textsuperscript{18} This feature is dominant in the NSF channel (Fig. 2a, middle). The [111]-rod scattering is accompanied by a branch from (111) to (220) in the SF channel (Fig. 2a, left), and by another from (222) towards (004) in the NSF channel (Fig. 2a, middle). The anisotropic nature of the spin correlations is clearly seen around (111) in the SF channel (Fig. 2a, left), suggesting a remnant of the pinch-point singularity that has been observed as a sharper singularity in dipolar spin ice.\textsuperscript{7,8} To examine this structure in more detail, we have performed similar measurements with a higher resolution at 0.3 and 1.5 K. Figure 2c,d show the neutron scattering cross-sections for the SF channel along [11-1] and [111] cuts, respectively, through the remnant of the pinch point (111) at $T = 0.3$ and 1.5 K. The data were measured with a higher resolution in reciprocal space than the full $(h,h,l)$ profiles. One or two points marking a high level of intensity at and close to the (111) point correspond to the nuclear Bragg peak. The lines are a guide to the eye. (a) Temperature dependence of the total cross-section along [11-1] cut through (1.5,1.5,1.5), as indicated in the inset.

Figure 2 | Magnetic diffuse neutron scattering profiles. The incident neutron spins were polarized along the $Z$ direction. (a) Experimentally observed profiles for the SF (left), NSF (middle) and total (right) magnetic diffuse neutron scattering cross-sections in the $(h,h,l)$ plane above $T_C$ at $T = 0.3$ K. The background levels for the diffuse scattering have been subtracted by making use of the data measured with the incident neutron beam polarized along the $X$ direction parallel to the scattering wavevector $Q$ (see Supplementary Methods and Supplementary Fig. S3). White circles mark the Bragg spots where the background subtraction scheme is less reliable. The measurements were performed in the energy-integrated diffraction mode up to an energy of 3.64 meV. (b) Theoretically calculated magnetic profiles for SF (left), NSF (middle) and total (right) magnetic diffuse neutron scattering cross-sections in the $(h,h,l)$ plane at $T = 0.3$ K. The profiles were obtained as the equal-time correlators in the RPA (Supplementary Methods) to the pseudospin-1/2 model, $H_0 + H_{se}$. The form factor is not included. (c,d) Neutron scattering intensity for the SF channel along [11-1] and [111] cuts, respectively, through the remnant of the pinch point (111) at $T = 0.3$ and 1.5 K. The data were measured with a higher resolution in reciprocal space than the full $(h,h,l)$ profiles. One or two points marking a high level of intensity at and close to the (111) point correspond to the nuclear Bragg peak. The lines are a guide to the eye. (e) Temperature dependence of the total cross-section along [11-1] cut through (1.5,1.5,1.5), as indicated in the inset.
These polarization-dependent anisotropic neutron scattering results are reproduced theoretically as follows. The Yb\( ^{3+} \) 4\( f \) magnetic moment at a site \( r \) is described with the ionic Kramers doublet\(^{22} \) and thus the pseudospin-1/2 operator \( S_\| = (S_\|^p, S_\|^p, S_\|^p) \) as \( \hat{m}_r = \mu_B (g_\| (S_\|^p e^\|_r + S_\|^p e^\|_r) + g_\| S_\|^p e^\|_r) \) with the locally defined coordinate frame \( (e^\|_r, e^\|_r, e^\|_r) \) (Supplementary Methods), where the \( Z \) axis points along the \( [111] \) direction. The effective Hamiltonian consists of the magnetic dipolar interaction,

\[
H_D = \frac{\mu_0}{4\pi} \sum_{\langle \mathbf{r}, \mathbf{r}' \rangle} \left[ \mathbf{m}_r \cdot \mathbf{m}_{r'} - \frac{3}{(\Delta \mathbf{r})^3} (\mathbf{m}_r \cdot \mathbf{\Delta r}) (\mathbf{m}_{r'} \cdot \mathbf{\Delta r}) \right],
\]

with \( \Delta \mathbf{r} = |\Delta \mathbf{r}| \), \( \Delta \mathbf{r} = \mathbf{r} - \mathbf{r}' \) and a nearest-neighbour anisotropic superexchange interaction\(^{16,19} \),

\[
H_{se} = \frac{J}{2} \sum_{\langle \mathbf{r}, \mathbf{r}' \rangle} \left[ \hat{\sigma}_r \hat{\sigma}_{r'} + \Delta \sigma_r \Delta \sigma_{r'} + Q e^{2i\phi_r \mathbf{r} \cdot \mathbf{r}'} \hat{\sigma}_r \Delta \sigma_{r'} + K e^{2\phi_r \mathbf{r} \cdot \mathbf{r}'} \Delta \sigma_r \Delta \sigma_{r'} \right] + h.c.,
\]

with the bond-dependent phase factor \( \phi_r \mathbf{r} \) (Supplementary Methods). Here, \( J \) is the coupling constant for the Ising interaction found in spin-ice systems\(^{10,15} \), whereas the dimensionless parameters \( \delta q \) and \( K \) represent the relative coupling constants of the planar quantum exchange interaction that respect/break the U(1) pseudospin symmetry and of another interaction that breaks the 2\( \pi \) rotation symmetry of the pseudospins about the \( [111] \) direction. Figure 2b shows the magnetic neutron scattering cross-sections calculated at \( 0.3 \) K within the random phase approximation (RPA)\(^{34} \). A set of four adjustable parameters \( (J, \delta q, K) = (0.68 \text{ K}, -0.8, 0.2, -1.0) \) reproduces the experimental profiles shown in Fig. 2a. (Any change of \( \delta q \) or \( K \) by \( \pm 0.1 \) gives worse results.) The signs and ratios of the coupling constants obtained from the fitting are comparable to those obtained microscopically with a reasonable ratio \( V_{p/r} / V_{p/o} = 0.2 \) of the Slater–Koster parameters\(^{19} \). The values of \( (\delta q, K) \) are also nearly within the error bars of the recent spin-wave analysis of high-field inelastic neutron scattering results\(^{20} \) (Supplementary Methods). The positive coupling constant \( J \) for the Ising interaction favours the 2-in, 2-out spin-ice manifold. (Note that the amplitude of \( J \) could be underestimated here because of an overestimation of the onset temperature for the instability in the RPA.) Accordingly, a macroscopic number of states are nearly degenerate, in spite of the additional interactions. In the theoretical calculations, the intensity and the sharpness of a remnant of the pinch-point singularity increase with decreasing temperature in the high-temperature paramagnetic phase (Supplementary Fig. S4), in qualitative agreement with our experimental results. These observations support the scenario that the high-temperature phase of Yb\( _2 \)Ti\( _2 \)O\( _7 \) in the temperature range \( T_C < T < 2J \) is well described as a classical magnetic Coulomb liquid, which hosts the pinch-point features and monopolar spinons that are deconfined with a finite excitation energy.

First-order transition to a ferromagnetic state. In Fig. 2e we present the temperature dependence in the sum of the SF and NSF magnetic neutron scattering cross-sections across the \( [111] \) rod through \((1,5,1,5,1,5)\). The broad intensity increases gradually on cooling from \( 0.7 \) to \( 0.3 \) K, but falls abruptly at \( 0.2 \) K, signalling a sudden change in the spin correlations. Actually, the neutron scattering profile at \( 0.04 \) K (Supplementary Fig. S3d) clearly shows that the \( [111] \) rod scattering loses intensity. We have measured the \( [111] \) Bragg peak intensity as a function of temperature on warming and cooling, with the incident neutron spins polarized along the \( X \) direction. Figure 3a shows the dependence of the sum of the SF and NSF channels for small angular deviations from the wavevector \( [111] \) (rocking-curve scans) both above and below \( T_C \) with the data collected on warming the sample. By subtracting the \( 1 \) K data, the magnetic components can be clearly observed below \( T_C \) (Fig. 3b). The integrated intensities for the SF and NSF channels (Fig. 3c) and for the sum of the two (Fig. 3d) show a remarkable hysteresis around \( T_C \), indicating a first-order magnetic phase transition. It is possible that the magnetic scattering intensity along the diffuse \([111]\) rod is removed to form the magnetic Bragg peaks below \( T_C \). Well above \( T_C \) the flipping ratio (the ratio of the NSF to SF cross-sections) at \( (111) \) gradually decreases on cooling and then falls more rapidly to unity around \( T_C \) (Fig. 3e). This indicates that the incident neutron spins are already partially depolarized in the high-temperature phase because of short-range ferromagnetic correlations, and are fully depolarized well below \( T_C \) pointing to the emergence of macroscopic ferromagnetic domains. Furthermore, the first-order nature of the transition has also been confirmed by a sharp anomaly in the specific heat of the sample, (Supplementary Fig. S1), which closely resembles the earlier result\(^{21} \).

The emergent ferromagnetic order without translational symmetry breaking is also understood theoretically by the mean-field analysis (Supplementary Methods) of the same model at \( T = 0 \) with the values of the dimensionless coupling constants \( (\delta q,K) \) determined above. It is found that the mean-field ground state has a non-coplanar pseudospin order with the Ising component \( S_\|^\| \sim 0.43 \) and the planar component \( (S_\|^p)^2 + (S_\|^p)^2 \sim 0.25 \), as shown in Fig. 1b. This is translated to a non-coplanar ferromagnetic order with a slight tilting from the \([100]\) direction by \(-1^\circ\) and a moment amplitude \( 1.3\mu_B \) (Fig. 1c), in fair agreement with the previous neutron diffraction results on the same single crystal\(^{31} \). These results on the direction and the amplitude of the magnetic moments also show reasonable agreements with previous Mössbauer results on a powder sample\(^{23} \).

In this low-temperature phase, no soft spin excitations exist because of the absence of a continuous symmetry in the original model. This slightly non-coplanar ferromagnetic ground state does not alter with \( (\delta q,K) \) within the accuracy of our fitting procedure.

Discussion

From the viewpoint of gauge theory\(^{2,28} \), the high-temperature phase of our system is effectively described as a Coulomb phase, where bosonic fractionalized quasi-particles, ‘spinons’, carrying magnetic monopole charges are deconfined without a static non-uniform proliferation of monopole charges and host fluctuating U(1) gauge fields responsible for the analogous ‘quantum electrodynamics’. These magnetic monopolar spinons can undergo a Bose-Einstein condensation\(^{32} \) to form the classical ferromagnetic moments\(^{28} \) (Fig. 1a). This pins the global U(1) phase of the spinon fields, and breaks the nontrivial emergent U(1) gauge structure. This condensation of matter (spinon) fields coupled to gauge fields occurs through the Higgs mechanism\(^{29} \). Thus, the ferromagnetic state can be viewed as a Higgs phase of magnetic monopoles.

Our observations support a novel picture that magnetic monopole charges are carried by fractionalized bosonic quasi-particles in the high-temperature magnetic Coulomb liquid. At present, the disappearance of the low-energy gapless excitation spectrum, unique to the Higgs phase, is only suggested by the long magnetic relaxation times seen in this and earlier studies\(^{24} \), and must be confirmed by future experiments, which could also identify the spectrum of gapped spin wave excitations having the role of ‘Higgs bosons’. It will also be fascinating to search for the quantum phase transition between the magnetic Coulomb phase and the Higgs phase with proper control of the material by pressure or chemical substitution.

Methods

Single-crystal growth. Single crystals of Yb\( _2 \)Ti\( _2 \)O\( _7 \), which were also used in the previous published work\(^{24} \), were prepared by the floating zone method. Stoichiometric quantities of Yb\( _2 \)O\( _3 \) and Ti\( _2 \)O\( _3 \) powder were mixed, pressed into rods and
Figure 3 | Hysteresis in the Bragg peak intensity and flipping ratio at (111). The data were collected on cooling and warming across \( T_C \) in the X-direction polarized neutron scattering experiments. To ensure that the system was in thermal equilibrium, measurements well below \( T_C \) were performed after waiting longer than the magnetic relaxation time, which is of the order of 2 h at 0.03 K (ref. 24). (a) The rocking-curve scans of the (111) Bragg peak for the sum of the SF and NSF channels measured while warming the sample. The horizontal axis represents the deviation of the wavevector from (111) with their amplitude being unchanged. The lines are a guide to the eye. All the peaks are instrument resolution limited. (b) The magnetic contribution to the (111) Bragg peak is obtained by subtracting the data measured at 1 K, which is well above \( T_C \) in the warming sequence. (c) The growth of the integrated intensity for the (111) Bragg peak begins abruptly below \( T_C \) with a discernible hysteresis in both the SF and the NSF channels. (d) The sum of the SF and the NSF (111) Bragg peak intensities versus temperature showing a hysteresis with temperature. The sum increases by almost 6% below \( T_C \) in agreement with the previous measurements\(^{24}\). (e) The flipping ratio of the neutron spins at the (111) Bragg peak as a function of temperature. This ratio falls off steeply to unity below \( T_C \) with a clear hysteresis. The data were collected by first warming and then cooling. This sequence is indicated by the arrows in (c–e).

Characterization of different single-crystal samples. Here, we discuss the controversy over the presence or absence of a first-order phase transition in Yb\(_2\)Ti\(_3\)O\(_7\). We then demonstrate from measurements of the specific heat and the EXAFS that the quality of the samples significantly alters the low-temperature behaviour of this material. In particular, we show that the long-range ferromagnetic order realized through the first-order phase transition in the single-crystal sample reported in the main text is easily removed by reducing the Yb content within the sample.

First, let us briefly summarize the previous experimental reports that catalogue the strong sample dependence of the physical properties of Yb\(_2\)Ti\(_3\)O\(_7\). The Curie–Weiss temperature, \( \Theta_{\text{CW}} \), varies considerably from sample to sample. \( \Theta_{\text{CW}} \approx 0.53 \) K for our sample reported on in the main text and in ref. 24, 0.40 K in ref. 21, 0.59 K in ref. 36 and 0.75 K in ref. 22. A significant sample dependence is also observed in the low-temperature specific heat in both powder and single-crystal Yb\(_2\)Ti\(_3\)O\(_7\) samples\(^{24, 37}\). In addition, according to Gardner et al.\(^{25}\), a magnetic Bragg peak was observed at (111) with polarized neutron scattering measurements on polycrystalline samples, although neutron spin depolarization was not observed and static ferromagnetic order was ruled out.

In an attempt to rationalize these conflicting reports, we have studied three single-crystal samples of Yb\(_2\)Ti\(_3\)O\(_7\) using specific heat and EXAFS measurements. Sample A was prepared using the method described above and was the sample used for both our polarized neutron scattering measurements and the previous unpolarized measurements\(^{24}\). Sample B was produced from a rod sintered at 1,350 °C rather than 1,150 °C, and was grown in air using a faster growth rate of 8 mm/h in 4 bars of oxygen and at a faster growth rate of \( 1.5 \) mm/h. The crystals had a typical diameter of ~6 mm and a length of 20 mm. Powder X-ray diffraction measurements on a pulverized part of the single crystal showed no appreciable amount of any impurity phase.

For comparison with other experimental work that reported the absence of long-range magnetic order, the different methods of sample preparation are worth mentioning. Only three reports are available in the literature. Gardner et al.\(^{25}\) synthesized polycrystalline samples of Yb\(_2\)Ti\(_3\)O\(_7\) by firing stoichiometric amounts of Yb\(_2\)O\(_3\) and TiO\(_2\) at 1,350 °C for several days, with the quality checked by X-ray diffraction. Ross et al.\(^{18}\) synthesized single crystals of Yb\(_2\)Ti\(_3\)O\(_7\) using the same floating zone method as our work, but in 4 bars of oxygen and at a faster growth rate of 8 mm/h. Single crystals prepared by Yaouan et al.\(^{35}\) were also grown by the floating zone method but at an even faster growth rate of 8 mm/h in air with and without a subsequent heat treatment for 24 h at 1,100 °C under oxygen flow.

Sintered at 1,150°C for 24 h. Using these rods, single crystals were grown in air at a rate of 1.5 mm/h. The crystals had a typical diameter of ~6 mm and a length of 20 mm. Powder X-ray diffraction measurements on a pulverized part of the single crystal showed no appreciable amount of any impurity phase.
5 mm/h (cf. Ross et al. who also used a faster growth rate but grew in 4 bars oxygen). Sample C was grown from another rod, which was prepared in the same manner as sample A. However, the molten zone was less stable during the crystal growth.

Supplementary Figure S1 shows the temperature variation of the specific heat for these three samples. Sample A has a sharp singularity at 0.214 K. This is consistent with the observation made in our neutron scattering experiments of the first-order phase transition to a ferromagnetic state. Similar sharp anomalies were also observed for polycrystalline samples in both the early and recent measurements.

Author contributions
L.J.C. performed the neutron scattering experiments and wrote the manuscript; S.O. and Y.J.K. performed the theoretical calculations and wrote the manuscript; Y.S. designed and performed the neutron scattering experiments; Y.Y. grew the single-crystal sample; K.K. and M.R.L. supervised the neutron scattering experiments. M.R.L. carried out the heat capacity measurements. K.D.T. performed the EXAFS studies. All the authors discussed the results and the manuscript.
