Abstract Cyanobacteria have developed responses to maintain the balance between the energy absorbed and the energy used in different pigment-protein complexes. One of the relatively rapid (a few minutes) responses is activated when the cells are exposed to high light intensities. This mechanism thermally dissipates excitation energy at the level of the phycobilisome (PB) antenna before it reaches the reaction center. When exposed to low intensities of light that modify the redox state of the plastoquinone pool, the so-called state transitions redistribute energy between photosystem I and II. Experimental techniques to investigate the underlying mechanisms of these responses, such as pulse-amplitude modulated fluorometry, are based on spectrally integrated signals. Previously, a spectrally resolved fluorometry method has been introduced to preserve spectral information. The analysis method introduced in this work allows to interpret SRF data in terms of species-associated spectra of open/closed reaction centers (RCs), (un)quenched PB and state 1 versus state 2. Thus, spectral differences in the time-dependent fluorescence signature of photosynthetic organisms under varying light conditions can be traced and assigned to functional emitting species leading to a number of interpretations of their molecular origins. In particular, we present evidence that state 1 and state 2 correspond to different states of the PB-PSII-PSI megacomplex.

Keywords Cyanobacteria • Spectrally resolved fluorometry • Singular value decomposition • Time-resolved spectroscopy

Introduction

Excess light is a hazard all photosynthetic organisms have to deal with (Demmig-Adams et al. 2014). Long-lived excited chlorophyll species lead to the formation of reactive oxygen species (ROS) that damage the photosystems and impair growth or even lead to death (Nishiyama et al. 2001). High-energy-dependent as well as light-adaptive mechanisms have evolved to cope with varying excitation energy fluxes (Papageorgiou 1996; Papageorgiou et al. 2007; Joshua and Mullineaux 2004; Mullineaux and Allen 1990, 1986). Cyanobacterium *Synechocystis* PCC 6803 (hereafter, *Synechocystis*) possesses a phycobilisome (PB) antenna that harvests mainly orange light which is hardly absorbed by photosystem I or PSII (Shevela et al. 2013). Also, a megacomplex of PB, PSII, and PSI has been described (Liu et al. 2013; Steinbach et al. 2015) in which the energy absorbed by PB can be transferred to PSII or PSI. In vivo, the abundance and the dynamics of excitation energy transfer in this megacomplex are still debated (Chukhutsina et al. 2015).
Non-photochemical fluorescence quenching (NPQ) at the level of the PB antenna has been observed when high photon fluxes photoconvert the orange carotenoid protein (OCP) to its red form (OCP\textsuperscript{r}) (Wilson et al. 2008) which then binds to the phycobilisome thereby inducing fluorescence quenching (Gwizdala et al. 2011). Cyanobacteria also regulate the supply of electronic excitations to PSI and PSII by means of state transitions (Kirillovsky et al. 2014; Mullineaux and Emlyn-Jones 2005; Vernotte et al. 1990; Kaňa et al. 2012). In state 1, the PB antenna transfers energy to PSII predominantly. As the electron transport chain from PSII to PSI gets reduced, a rearrangement of the building blocks in and around the thylakoid membrane allows the antenna to supply PSI with more and PSII with less energy. This is the state 1 to state 2 transition. In darkness, \textit{Synechocystis} cells have been reported to be in state 2 due to the respiratory activity (Campbell et al. 1998; Liu 2015; Mullineaux 2014). Changes in fluorescence allow us to follow the activation (as well as deactivation or persistence) of the mechanisms described above.

The spectral properties of the different subunits of the cyanobacterial photosynthetic apparatus have been studied in the past (see e.g., Komura and Itoh (2009) and references therein). The presence of phycocyanin (PC) and allophycocyanin (APC) in the PB antenna leads to emission in the 655 and 670 nm regions (Glazer and Bryant 1975; Cho and Govindjee 1970; Gwizdala et al. 2011). After excitation of the PB with 590 nm light, energy transfer to the photosystems I and II results in Chl a emission around 680–690 nm (Tian et al. 2011). The spectral evolution of the fluorescence on the ps and ns time scales thus results in a steady-state spectrum characteristic, for e.g., the PB-PSII complex.

For a systematic study, given the multiplicity and a variety of mechanisms cyanobacteria possess to control the photosynthetic electron transport (Kirillovsky et al. 2014; Liu 2015; Govindjee and Shevela 2011), we have used model systems: (i) an in vitro experiment, where the OCP-induced energy dissipating mechanism was reconstituted and (ii) two mutants of \textit{Synechocystis}, lacking either PSI (ΔPSI) or PSII (ΔPSII). Such model systems are expected to generate simplified signals in comparison to the complete in vivo system and allow us to validate the new method of analysis. They provide important contributions to understanding the bigger picture, i.e., that of the wild-type organism.

These processes can be investigated using spectrally resolved fluorometry (SRF) using a set-up with multiple independently controllable excitation sources, e.g., LEDs with various spectral profiles (Lambrev et al. 2010). In this configuration, one LED can be used to acquire full fluorescence spectra using a specific light intensity and spectral profile, whereas a second LED can be used to induce changes to the photosynthetic apparatus using a different intensity or different spectral characteristics. The result is a data matrix that displays levels of fluorescence emission as a function of wavelength and time (Kaňa et al. 2012; Kaňa et al. 2009; Lambrev et al. 2010). In this work, the data matrices are then analyzed with a model-based approach, assuming that at any timepoint, the spectra can be described as a linear combination of species-associated spectra (SAS). The SAS are the same for all time points, but their relative contributions vary with time. In contrast to PAM signals, where all fluorescence above 700 nm is integrated, the time-resolved spectrum can be analyzed to resolve the SAS and the time-dependent contributions of the different species, leading to a number of interpretations of their molecular origins.

Materials and methods

Isolated PB and OCP to form quenching complexes

Isolation of PB and OCP is described in detail in Gwizdala et al. (2011). PBs were stored and examined in a 0.8 M potassium phosphate buffer. In this experiment, the molecular ratio between the PBs and OCP was 1:37 (±1).

Cell cultures

For experiments with closing of PSII RCs in vivo (as described in the “Closing of reaction centers during fluorescence induction by saturating light in vivo” section), we used wild-type \textit{Synechocystis} PCC 6803 (a glucose-tolerant derivative) kindly provided by Devaki Bhaya (Department of Plant Biology, Carnegie Institution for Science, Stanford, California, USA); it was cultivated in a modified BG-11 medium (Stanier et al. 1971) in a photobioreactor [model FMT 150.2/400, Photon Systems Instruments; for details, see Nedbal et al. (2008)] as previously described by van Alphen and Hellingwerf (2015). BG-11 was supplemented with 10 mM NaHCO\textsubscript{3}. A mixture of CO\textsubscript{2} in N\textsubscript{2} (150 mL min\textsuperscript{-1}) was used to provide a constant supply of CO\textsubscript{2}; the pH was set to 8.0 by automatically adjusting the pCO\textsubscript{2} using a gas mixing system (GMS150, Photon Systems Instruments). The photobioreactor was run as a turbidostat, which allowed continuous growth at a set optical density (OD) at 730 nm of 0.4 ± 2 % (OD\textsubscript{730} = 1 ± 10\textsuperscript{6} cells mL\textsuperscript{-1}), as measured by a benchtop photospectrometer (Lightwave II, Biochrom). Seventy-five μmol of photons m\textsuperscript{-2} s\textsuperscript{-1} of orange-red light (λ\textsubscript{max} 636 nm, 20 nm full-width at half-maximum) was provided to the cells, using an integrated LED panel, which yielded a doubling time of approximately 9 h. The temperature was set to 30 °C and maintained to within 0.2 °C. For other
experiments, described in the “In vivo fluorescence induction with orange light in wild-type and PSI-, and PSII-deficient mutants of Synechocysts” section, we used freshwater cyanobacteria Synechocystis PCC 6803 (wild-type and its mutants); they were cultivated in BG 11 medium, in an orbital shaking incubator, at 28 °C and at a constant irradiance of 40 μmol of photons m⁻² s⁻¹ of PAR (photosynthetically active radiation, 400–700 nm). The specific mutants without PSI [ΔPSI, without PsAa and PsAB proteins; for details, see Shen et al. (1993)] or without PSII [ΔPSII without CP47 and CP43 proteins and with at most 10 % of PSII-RC; for details, see Komenda et al. (2004)] were used for our measurements.

**Time-resolved fluorescence spectra at room temperature**

Two set-ups were employed, one in Amsterdam and the other in Tréboň. The set-up in Tréboň has been described by Kaňa et al. (2009) and it was used for experiments presented in the “In vivo fluorescence induction with orange light in wild-type and PSI-, and PSII-deficient mutants of Synechocystis” section. The set-up that was used in Amsterdam to track PB fluorescence quenching in vitro (“OCP-related PB fluorescence quenching in vitro” section) and closing of RCs in vivo (“Closing of reaction centers during fluorescence induction by saturating light in vivo” section) is described here. This set-up has been originally developed for measurements on leaves. A detailed description can be found in Lambrev et al. (2010). A modified geometry allowed full fluorescence spectra to be acquired from samples in solution (Figure S1A). LEDs of several spectral characteristics can be easily interchanged as needed for a specific light protocol (Figure S1B). During the quenching experiments on isolated PB (“OCP-related PB fluorescence quenching in vitro” section), orange light (590 nm; 300 μmol of photons m⁻² s⁻¹) was used as measuring light (ML), while for OCP pre-conversion (placed in a bath at 4 °C) to OCP⁺, high-intensity white light (5000 μmol of photons m⁻² s⁻¹) was used (Gwizdala et al. 2011). The measurement protocol consists of, first, continuous exposition of the isolated PB to ML, then addition, in one step, of OCP to the PB. In the case of the in vivo measurement (“Closing of reaction centers during fluorescence induction by saturating light in vivo” section), cells were exposed to 1500 μmol of photons m⁻² s⁻¹ of orange light during one second. In both the cases, the signals were collected (integration time) every 100 ms. In addition, a very low-intensity experiment was carried out with 1 μmol of photons m⁻² s⁻¹ of orange light during one minute and integration time of 10 s. Fluorescence is collected via a lens that focuses them into a fiber connected to a CCD spectrometer (USB2000+, OceanOptics). Home-made protocols written in National Instruments LabView and Wolfram Mathematica were used to carry out the data acquisition and the data analysis, respectively.

**Protocol for spectrally resolved fluorescence induction measurements on intact living cells**

Fluorescence experiments to monitor state transitions were performed by means of a spectrally resolved fluorescence induction (SRFI) method (Kaňa et al. 2009). In the “In vivo fluorescence induction with orange light in wild-type and PSI-, and PSII-deficient mutants of Synechocystis” section, fluorescence emitted by whole Synechocystis cells was sampled every 90 ms under continuous illumination for a period of 12 min. Experiments were made with control cells without inhibitors (non-treated, hereafter) and those treated with 3-(3’,4’,5’-trichlorophenyl)-1,1-dimethylurea (DCMU), as described previously in Kaňa et al. (2012). Cells were dark adapted for 20 min before SRFI measurements to induce state 2. The maximal fluorescence [Fm or, if light-adapted, Fm′] for details of nomenclature, see Krause and Weis (1991)] reflecting full closure of the PSII reaction centers was induced by a saturation light pulse (590 nm; At 200 ms; 1200 μmol of photons m⁻² s⁻¹). The first and last pulses were applied during a period of darkness. The evolution of the spectrally resolved fluorescence signal, induced by orange actinic irradiation, was then measured during 10 min.

**Analysis of the data matrix**

Acquired fluorescence spectra (n wavelengths) at m time points can be represented by an (m × n) data matrix Ψ. Below, we describe the procedure to extract species-associated spectra (SAS) and their time evolution.

The singular value decomposition (SVD) procedure (Golub and Van Loan 1996) decomposes Ψ according to

\[ Ψ = U \cdot S \cdot V^T \]  

(1)

into an (m × m) matrix U, where the m columns are called the left singular vectors (lsv); the (m × n) diagonal matrix S whose diagonal elements (s₁, s₂, s₃, ...) are called the singular values and the transpose of the (n × n) matrix V, Vᵀ, where the n rows are called the right singular vectors (rsv). In this study, the data matrix is constituted by spectra arrayed in time. Hence, the rsv which are significantly different from the noise are a linear combination of the SAS and the accompanying lsv are a linear combination of their time-dependent concentrations. We seek a mathematical transformation to resolve these SAS and their concentrations.

The original matrix Ψ can be satisfactorily reconstructed by means of the most significant singular vectors. A matrix
is of rank \( n \) if \( n \) singular values differ significantly from the singular values that represent the noise. The rank of the data matrix is determined after visual inspection of the logarithmic plot of the diagonal elements of \( S \) (also called scree plot, e.g., Fig. 1) and of the singular vectors (e.g., Figure 1c, d). When the scree plot indicates that the data matrix is of rank 2, a matrix \( A \)

\[
A = \begin{pmatrix}
1 & a_{12} \\
a_{21} & a_{21} \cdot a_{22}
\end{pmatrix}
\]

(2)

is introduced in Eq. 1 to write the decomposition of the data matrix as

\[
\Psi = U \cdot S \cdot (A^{-1} \cdot A) \cdot V^T
\]

(3)

The aim is to find a biophysically meaningful solution by tuning the coefficients \( a_{12}, a_{21}, \) and \( a_{22} \). We note in Eq. 3 that \( A \) operates on the \( \text{rsv} \), whereas \( A^{-1} \) operates on \( U \cdot S \), i.e., the \( \text{lsv} \) scaled by \( S \). The SAS are obtained after this transformation of the \( \text{rsv} \). Explicitly, they fulfill

\[
\begin{pmatrix}
\text{SAS}_{k1} \\
\text{SAS}_{k2}
\end{pmatrix} = AV^T = \begin{pmatrix}
1 & a_{12} \\
a_{21} & a_{21} \cdot a_{22}
\end{pmatrix} \begin{pmatrix}
v_{1k} \\
v_{2k}
\end{pmatrix}
\]

(4)

where the second index \( k \) indicates that \( v_{1k} \) and \( v_{2k} \) are row vectors of length \( n \) (wavelengths). Expansion of Eq. 4 leads to two equations that can be written as follows:

\[
\begin{align}
\text{SAS}_{k1} &= v_{1k} + a_{12} \cdot v_{2k} \\
\text{SAS}_{k2} &= a_{21} (v_{1k} + a_{22} \cdot v_{2k})
\end{align}
\]

(5)

where the respective coefficients acquire the following meaning: \( a_{12} \) is the spectral shape factor of \( \text{SAS}_{k1} \), \( a_{22} \) is the spectral shape factor of \( \text{SAS}_{k2} \), and \( a_{21} \) is a scaling factor that tunes the relative amplitudes of \( \text{SAS}_{k1} \) and \( \text{SAS}_{k2} \). Using the inverse of \( A \),

\[
A^{-1} = \frac{1}{a_{21}(a_{22} - a_{12})} \begin{pmatrix}
a_{22} - a_{12} & -a_{12} \\
a_{21} & 1
\end{pmatrix}
\]

(6)

we compute the matrix \( C = U \cdot S \cdot A^{-1} \), that contains two column vectors for the concentrations \( c_{1t} \) and \( c_{2t} \) of length \( m \) (time points). Their explicit expression, according to Eq. 6, is:

\[
\begin{align}
c_{1t} &= \frac{a_{22} \cdot s_{1} \cdot t_{1} - s_{2} \cdot t_{2}}{a_{22} - a_{12}} \\
c_{2t} &= \frac{s_{2} \cdot t_{2} - a_{12} \cdot s_{1} \cdot t_{1}}{a_{21}(a_{22} - a_{12})}
\end{align}
\]

(7)

Hence, the final decomposition of a rank 2 data matrix \( \Psi \) can be expressed as the linear combination of these two concentrations and SAS:

\[
\Psi = c_{1t} \text{SAS}_{k1} + c_{2t} \text{SAS}_{k2}.
\]

(8)

To judge whether the transformation yields a biophysically meaningful solution, the following four criteria are used: (i) non-negativity of the SAS, (ii) non-negativity of their difference (SAS\(k_1\)–SAS\(k_2\)), (iii) non-negativity of the concentrations, and (iv) constancy of their sum (\( c_{1t} + c_{2t} \)) during constant excitation. For a rank two matrix, criterion \( iv \) is equivalent to the assumption that an excitation can only be emitted either as \( \text{SAS}_{k1} \) or \( \text{SAS}_{k2} \). When the number of excitations created is constant, this means that the sum of concentrations is constant.

![Fig. 1](image-url) Visualizing the acquired dataset (a, b) and SVD (c, d) after a quenching experiment on isolated PB and pre-converted OCP’ (added at \( t = 18 \) s). The data matrix was obtained after continuous illumination of isolated PB in 0.8 M phosphate buffer with 590 nm light (300 \( \mu \)mol photons \( m^{-2} \) \( s^{-1} \)). Fluorescence spectra were acquired every 100 ms. For selected timepoints, acquired spectra in the range 640–800 nm (b) and time courses (a) are shown.

Key to a) black 640 nm, gray 653 nm, maroon 666 nm, brown 678 nm, red 691 nm, orange 703 nm. Key to b) black 0.3 s, gray 7.2 s, maroon 14.1 s, brown 21.0 s, red 27.9 s, orange 34.8 s. To this data matrix, we apply the SVD described by Eq. 1. The scree plot of the first 10 diagonal elements of \( S \) is shown in e, c and d display the first three \( \text{lsv} \) and \( \text{rsv} \) in black, red and gray, respectively.
For richer data featuring a matrix of rank 3 (or higher), additional criteria would be needed to determine eight (or more) coefficients $a_{ij}$.

**Results and discussion**

Our spectra-decomposing method and analysis protocol were applied to two well-defined systems under different conditions. The first system studied (“OCP-related PB fluorescence quenching in vitro” section) is in vitro quenching of PB fluorescence by pre-converted OCP, where only two states were expected (quenched and unquenched PB). The second system is the spectral transition during a single saturation pulse of white light with intact WT *Synechocystis* cells in vivo (“Closing of reaction centers during fluorescence induction by saturating light in vivo” section). These two systems are discussed in the following two sections. Each section consists of (i) description of the light protocol, (ii) description of the results, and (iii) conclusions. Based on this, the method is applied to more complex datasets of intact living cells acquired during orange light irradiation (“In vivo fluorescence induction with orange light in wild-type and PSI-, and PSII-deficient mutants of *Synechocystis*” section).

**OCP-related PB fluorescence quenching in vitro**

The OCP–PB interaction has been reconstituted and characterized in vitro (Gwizdala et al. 2011; Jallet et al. 2012; Wilson et al. 2012). In particular, the effects on the kinetics of fluorescence quenching as a function of OCP/PB ratio have been investigated using a PAM fluorometer and we present here one of the protocols with the aim of validating our method (see the “Time-resolved fluorescence spectra at room temperature” section). What we expect to see is: evidence for PB in either an unquenched (before OCP is added) or a quenched state (once OCP binds to the PB core) (Gwizdala et al. 2011).

First, a selected visualization of the acquired data matrix is depicted in Fig. 1. Time-dependent fluorescence levels at specific wavelengths (Fig. 1a) and selected spectra at specific time instants (Fig. 1b) are shown. From these data, we can qualitatively conclude that the PB fluorescence is reduced upon binding of OCP.

Figure 1c–e shows the results of SVD (see Eq. 1) of the data matrix. Panel $e$ is the scree plot from which we conclude that the data matrix is of rank 2. In other words: only the first two $lsv$ and $rsv$ contribute with information distinguishable from the noise. Panels c and d illustrate this clearly: the first three $lsv$, $u_{11}$, $u_{12}$, and $u_{13}$ and the first three $rsv$, $v_{1k}$, $v_{2k}$, and $v_{3k}$ are displayed in black, red, and gray, respectively. Clearly, the third components ($u_{13}$ and $v_{3k}$, in gray) are not distinguishable from the noise.

As a next step, a set of transformation coefficients (see Eq. 4) is determined to find the two characteristic SAS 1 and SAS 2 (SAS1 and SAS 2 hereafter) and their concentrations $c_{t1}$ and $c_{t2}$ ($c_1$ and $c_2$ hereafter). The result is shown in Fig. 2. The concentration profiles are shown in Fig. 2a with an orange bar indicating continuous illumination with orange light. The inset shows the percent deviation of the sum of concentrations from the average. Figure 2b shows the SAS, that we call SAS 1,PBis and SAS 2,PBis hereafter (is = isolated). The difference between SAS 1,PBis (black) and SAS 2,PBis (red) is shown in the inset in green. The criteria to accept this result have been a) the non-negativity of both concentration profiles $c_1$ and $c_2$, b) a near-zero $c_2$ before addition of OCP, c) a sum of concentrations that deviates only 2 % from the average (inset), and d) non-negative SAS. OCP has been added at $t \approx 18$ s. Before

---

The colored bar on top illustrates the light regime: 300 µmol photons m$^{-2}$ s$^{-1}$ of 590 nm light; Inset The sum of concentrations remains fairly constant with 2 % of maximal variation from the average. b Species-associated spectra SAS 1,PBis (black) and SAS 2,PBis (red). Transformation coefficients were set to $a_{12} = -0.40$, $a_{21} = 6.35$, and $a_{22} = -0.01$. Inset Difference spectrum SAS 1,PBis–SAS 2,PBis normalized to its maximum (665 nm)
this time point, only SAS$_{1,\text{PBis}}$ contributes to the signal. Upon addition of OCP$^\text{r}$ and formation of the quenching complex PB-OCP$^\text{r}$, an increase of $c_2$ (corresponding to SAS$_{2,\text{PBis}}$) at the expense of a decrease in $c_1$ is observed and confirms reported kinetics (Gwizdala et al. 2011). We therefore conclude that SAS$_{1,\text{PBis}}$ is the unquenched, while SAS$_{2,\text{PBis}}$ is the quenched form of the isolated PB. Both are in a good agreement with emission spectra of (un)quenched PB reported in the past (Tian et al. 2012; Jallet et al. 2012; Gwizdala et al. 2011).

Closing of reaction centers during fluorescence induction by saturating light in vivo

It is well known that a photosynthetic organism, when illuminated, displays a polyphasic increase in fluorescence (Kautsky and Hirsch 1931). After numerous reviews on the Kautsky effect, it has become common to speak about the so-called O-J-I-P steps of fluorescence induction (Lázár and Jablonský 2009; Stirbet et al. 2014; Govindjee 1995; Schansker et al. 2006; Stirbet and Govindjee 2011, 2012). Furthermore, slower transient characteristics (S-M-T) have also been observed and monitored (Kodru et al. 2015; Kaňa et al. 2012; Papageorgiou et al. 2007; Kaňa et al. 2009; Papageorgiou and Govindjee 2011). Our goal is to show how our analysis resolves, if any, contributions of different species during the OJIP regime, i.e., within the first second of illumination.

The action of a single saturation pulse on dark-adapted Synechocystis cells has been investigated: a high-intensity orange pulse is applied during 1 s, while the fluorescence response is integrated every 100 ms (see “Time-resolved fluorescence spectra at room temperature” section). We expect to observe PSII activity only given that PSI not only does not display any closure dynamics, as PSII does, but it also contributes very little to the signal. The SVD is shown in Figure S2. The scree plot (Figure S2c) shows two singular values distinct from the noise. After multiplication with the A matrix, SAS$_{1,\text{sat}}$ (black) and SAS$_{2,\text{sat}}$ (red) as well as their time evolution are obtained (Fig. 3b). We note that, during the first 300 ms, $c_2$ steadily decreases until it reaches a zero concentration (Fig. 3a). Concomitantly, $c_1$ increases reaching a plateau for $t > 0.3$ s. The typical inflection points of the OJIP-curve cannot be assessed due to the integration time of 100 ms. Note, however, that full closure of the RCs is only achieved after $\approx 300$ ms which lies within the expected time scale (Papageorgiou et al. 2007; Krause and Weis 1991; Neubauer and Schreiber 1987; Schreiber and Neubauer 1987). The difference spectrum clearly points at Chl $a$ fluorescence, which could be explained by closure of PSI RCs. Therefore, we conclude that SAS$_{2,\text{sat}}$ is a PB-PSII complex with open PSII RCs (PB-PSII$^\text{open}$), while SAS$_{1,\text{sat}}$ is a PB-PSII complex with closed PSII RCs (PB-PSII$^\text{closed}$). We support this interpretation with an independent measurement carried

**Fig. 3** Decomposition of the time-resolved fluorescence spectrum from whole cells of wild-type *Synechocystis* during a saturation flash of white light (1300 μmol photons m$^{-2}$ s$^{-1}$) illustrated by the yellow bar. **a** Concentration profiles of the two components $c_1$ (black) and $c_2$ (red). Inset The sum of concentrations remains fairly constant within $\pm 1$ % of maximal variation from the average. **b** Species-associated spectra SAS$_{1,\text{sat}}$ (black) and SAS$_{2,\text{sat}}$ (red) after transformation coefficients were set to $a_{21} = -0.014$; $a_{22} = 0.64$; $a_{22} = 0.38$. Inset Difference spectrum SAS$_{1,\text{sat}}$–SAS$_{2,\text{sat}}$ normalized to its maximum (682 nm). **c** For comparison normalized SAS$_{2,\text{sat}}$ from panel b (red) and SAS from an independent, very low-intensity experiment on whole cells of *Synechocystis* (black).
out with very low intensity and very long integration time (1 μmol of photons·m⁻²·s⁻¹; 10 s). The data matrix obtained under these illumination conditions was of rank 1 and the signal is expected to originate predominantly from PB-PSII complexes with open PSII RCs. Note that the black curve in Fig. 3c agrees well with SAS₂, sat.

Summarizing, with the help of isolated systems the SAS of the (un)quenched isolated phycobilisome antenna could be estimated, and, by applying a single saturation pulse on intact WT Synechocystis cells, a PB-PSII complex in the open state could be distinguished from one in the closed state.

**In vivo fluorescence induction with orange light in wild-type and PSI-, and PSII-deficient mutants of Synechocystis**

After having analyzed data obtained with simple protocols, the method was applied to analyze more complex experiments performed on whole cells of Synechocystis: these are continuously exposed to orange light of 300 μmol of photons·m⁻²·s⁻¹ throughout the measurement and to 1500 μmol of photons·m⁻²·s⁻¹ of the same light during the saturation flashes (clearly distinguishable peaks in the figures described below).

The data matrices are of rank 2 (see Figures S3–5). The analysis of the Synechocystis ΔPSII mutant yields the results as shown in Fig. 4. We associate SAS₁,ΔPSII with PB emission and SAS₂,ΔPSII with a quenched form of the PB. To resolve its origin, more datasets are necessary, however, given (i) the lack of fully assembled PSII RCs in this particular mutant and supported by (ii) the high amount of PSI complexes typically present in cyanobacterial thylakoids (Melis 1989; Moal and Lagoutte 2012; Shevela et al. 2013), a direct transfer from PB to PSI could be the origin of the quenching. Moreover, there is no DCMU-related effect on the dynamics (panel c of Figure S6). This is a sensible observation: DCMU is expected to block transfer from QA (the primary quinone electron acceptor of PSII) to the plastoquinone pool (PQ) by binding to the QB site of the D1 protein (Krause and Weis 1991). Indeed, in a system where fully assembled PSII is absent, the use of DCMU should trigger no response from the PSII complex. It should be noted that the PSII mutant contains small amounts of PSII-core complexes [less than 10 % in comparison to WT; see Komenda et al. (2004)]. The influence of such remainders, however, is negligible.

The results obtained for the ΔPSI mutant are summarized in Figs. 5, S4 and S7. The SAS₁,ΔPSI (black) spectrum strongly differs from SAS₁,ΔPSII due to the presence of PSII.
RCs. In analogy to our interpretation of SAS$_{1,sat}$, we interpret SAS$_{1, ΔPSI}$ as PB-$PSII_{closed}$. The SAS$_{2, ΔPSI}$ spectrum has a relative amplitude that strongly suggests a quenched PB. The highest $c_2$ values were reached via the saturation flashes during darkness (see first and last pulses in Fig. 5b). This contrasts with its rather small amplitude during the initial phase of orange light; it increased only slowly on light, reaching a steady level within $\approx 100$ s (see zoom panel in Fig. 5c). This would have to involve an unknown, and rather untypical, quencher X that competes with energy transfer to PSII RCs in darkness (e.g., non-activated centers) and that is slowly activated by light on prolonged periods of irradiation. Interestingly, the concentration of SAS$_{2, ΔPSI}$ remained maximal even during the light period in the presence of DCMU to close PSII (cf. Fig. S7c). One possibility for this rather untypical quencher may be a high light-inducible polypeptide (HliP), since (i) they presumably act as photoprotective players (He et al. 2001; Daddy et al. 2015; Komenda and Sobotka 2016) and (ii) they are overexpressed under various stressed conditions, including PSI deletion (see review by Komenda and Sobotka (2016) and references therein). Recently, quenching of Chl $a$ Q$_s$ by means of direct energy transfer to the S$_1$ state of $\beta$-carotene in an HliP has been shown by Staleva et al. (2015). It suggests, indeed, involvement of an HliP protein in the quenching in the ΔPSI mutant.

The results obtained for the WT cells are summarized in Fig. 6, S5 and S8. In this case, $c_1$ exhibits the slow S to M (to T) transition (Fig. 6c) related to the state 2 to 1 transition (Kaňa et al. 2012). As for the nature of the SAS, we associate SAS$_{1,WT}$ with PB-$PSII_{closed}$. The SAS$_{2,WT}$ features a quenched, hybrid form: it appears quenched relative to SAS$_{1,WT}$ and its shape does not entirely match those of SAS$_{2, ΔPSI}$ or SAS$_{2, ΔPSII}$. Also, we note that the ratio F650/F680 in SAS$_{1,WT}$ remarkably differs from that of SAS$_{1, ΔPSI}$. This is demonstrated in Fig. 7, where SAS$_{1,WT}$ has been scaled such that the respective regions below 650 nm (associated with PC emission from the PB antenna) overlap. In both cases, SAS$_{1, ΔPSI}$ and SAS$_{1,WT}$, have been assigned to PB-$PSII_{closed}$. How to explain the striking difference uncovered by Fig. 7 then? We put forward the following hypothesis: SAS$_{1, ΔPSI}$ would be interpreted as a pure species PB-$PSII_{closed}$, since the system consists of PB and PSII only. When PSI is added to the complex, as it is in WT, excitation energy can be transferred to PSI, where it is efficiently quenched. As a result, the 680 nm emission of the PSII with closed RCs is reduced, yielding SAS$_{1,WT}$. We call this mildly quenched by PSI. Before the state 2 to state 1 transition takes place, $c_2$ reaches a maximum (minimum of $c_1$ indicated by “S” in Fig. 6c) due to an increased excitation energy transfer rate to PSI. Therefore, in our interpretation, SAS$_{2,WT}$, where there is little 680 nm emission left, is the signature of a strongly quenched...
complex. This interpretation is in agreement with the previously reported PB-PSII-PSI megacomplex (Liu et al. 2013). Our current method is not able to discard alternative models for state transitions that involve, for instance, spill-over, i.e., the direct energy transfer from PSII to PSI (McConnell et al. 2002; Kirilovsky et al. 2014). We argue, however, that small nano-scale “switching”-like re-arrangements of these super complexes between a complex with a mildly/strongly coupled quencher could provide a fundamental clue on the mechanism of the state transition. These interpretations are also in line with the much faster increase/decrease in the SAS1,WT/SAS2,WT component with DCMU (see panel C in Figure S8). State 2 to 1 transition acceleration with this inhibitor has been, indeed, reported by Kaňa et al. (2012).

Our interpretations are summarized in Fig. 8. Phyco-bilisomes, PSII dimers, and PSI trimers are represented in a cartoon-like manner and not to scale. Energy transfer from the PB rods to the PB core, and from the PB core to the PSI and PSII units is illustrated by black arrows, whose size is an indication of its efficiency. For instance, based on quantitative analysis performed by Tian et al. (2011), we represent energy transfer times (e.g., from the PB rods to the PB core) on the order of 100 ps with a slim arrow, whereas faster energy transfer times (from the terminal emitters in the PB core to PSII) are represented by a thick arrow. Note that back transfer rates (from the PB core to the PB rods and from PSII to the terminal emitters in the PB core) are an order of magnitude smaller, and have been omitted in the cartoons. Thus, in the bottom row, the difference between SAS1,WT and SAS2,WT is visualized as an increase in the transfer rate from the PB core to PS I. This hypothesis remains to be tested.

Fig. 6 Analysis of the time-resolved fluorescence spectrum of non-treated WT cells. a Estimated SAS1,WT (black) and SAS2,WT (red); b the concentration profiles c1 (black) and c2 (red); c zoom into a region of b, d the normalized difference spectrum between black and red; e sum of the concentrations c_{total}; f zoom into a region of e. Transformation coefficients: a_{12} = 0.16, a_{21} = 0.51 and a_{22} = -0.15 (see detailed explanation in the main text). The SVD and full analysis of this dataset are shown in Figs. S5 and S8, respectively.

Fig. 7 Overlay plot of the SAS1,WT and SAS1,ΔPSI. The scaling is such that the respective blue edges (associated with PC emission) overlap.
Conclusions

We have presented in this paper a method to analyze time-dependent spectrally resolved fluorometry data, acquired using a multi-source fluorometer set-up. We have shown that in all cases presented here, the data can be decomposed into two SAS and their time evolution. By first applying the method to datasets acquired by means of simple protocols (isolated PB during OCP-induced quenching, WT cells during a saturation flash), the SAS of isolated un/quenched PB and PB-PSII complexes in either open or closed state have been determined.

This method was then applied to WT and selected mutants of *Synechocystis* during different light conditions.

Fig. 8 Proposed interpretation of the SAS obtained in the analysis of all samples. The inferred species shown are represented next to each pair of SAS. **Top** The ΔPSII mutant data feature unquenched PB and quenched PB via PSI. **Center** The ΔPSI mutant data feature a PB-PSII complex in closed state in an unquenched or a quenched state [probably by a high light-inducible protein, cf. Komenda and Sobotka (2016)]. **Bottom** In the WT, the presence of PSI and PSII leads to formation of a PB-PSII-PSI megacomplex (Liu et al. 2013) that can be either *mildly* or *strongly* quenched. Arrows indicate the flow of energy from the PB rods to the PB core cylinders, and from there to PS II or to PS I. The width of an arrow indicates the rate of energy transfer [estimated after Tian et al. (2011)]
In these cases, too, data matrices were well approximated by rank two matrices and for each pair of derived SAS, hypotheses about their molecular origin based upon the existing literature and sensible assumptions have been put forward. These interpretations are summarized in Fig. 8. The most striking finding concerns the difference between the respective SAS1 of WT and the ΔPSI mutant (see Figs. 7, 8) which we interpret as evidence for mild quenching by PSI in the WT PB-PSII-PSI megacomplex. While in state 2, the energy transfer to the PSI moiety of the megacomplex accelerates resulting in the quenched second SAS of WT (see Figs. 6 and 8). The wealth of information hidden in the SAS and the time traces of their concentrations presented here calls for the development of models at the molecular level to solidify their interpretation.

Acknowledgments  AMA gratefully acknowledges Michael Reus for his valuable assistance in re-building the set-up in Amsterdam. Prof.dr. K. J. Hellingwerf and dr. F. Branco dos Santos are thanked for critical reading of the text and helpful discussions. The anonymous reviewers are especially thanked for their helpful comments. Jaroslav Krafl is thanked for carrying out spectrally resolved fluorescence measurements in Trébon with cyanobacteria mutants. These mutants were kindly provided by Josef Komenda and Martin Tichý from Trébon’s laboratory (ΔPSII, ΔPSI); the ΔPSI mutant was originally constructed by Wim Vermaas (Arizona State University, Tempe, Arizona, U.S.). This research was performed as part of the BioSolar Cells research programme, sponsored by the Dutch Ministry of Economic Affairs. This work is part of the research programme of the Foundation for Fundamental Research on Matter (FOM), which is part of the Netherlands Organisation for Scientific Research (NWO). MG, IHMvS, and RvG acknowledge financial support of the European Research Council (Advanced Grant Proposal 267333 (PHOT-PROT) to RvG). RvG was further supported by the NWO-CW via a TOP-Grant (700.58.305), and by the EU FP7 Project PAPETS (GA 323901).
