Abstract. We propose a strategy for approximating Pareto optimal sets based on the global analysis framework proposed by Smale (Dynamical systems, New York, 1973, pp. 531–544). The method highlights and exploits the underlying manifold structure of the Pareto sets, approximating Pareto optima by means of simplicial complexes. The method distinguishes the hierarchy between singular set, Pareto critical set and stable Pareto critical set, and can handle the problem of superposition of local Pareto fronts, occurring in the general nonconvex case. Furthermore, a quadratic convergence result in a suitable set–wise sense is proven and tested in a number of numerical examples.

Key words. Multiobjective optimization, Pareto critical set, Delaunay tessellations in general dimension, stability of mappings

AMS subject classifications. 90C29, 58K25

1. Introduction.

1.1. Multiobjective optimization and Pareto optimality. Multiobjective optimization is concerned with the problem of optimizing several functions (or objectives) simultaneously. A precise mathematical statement in an economical framework was first given by V. Pareto [36, 37] in the 1880’s. In recent years a strong interest has grown, as a variety of problems in structural mechanics, automotive, aerospace, production planning, environmental policy and many others, involve more than one objective function and different numerical strategies have been developed subsequently [32].

In the single objective case, an optimum is defined as a point \( x \in W \subseteq \mathbb{R}^n \) where a given function \( u : W \to \mathbb{R} \) assumes its maximum, if the maximum exists. In multiobjective optimization we consider two or more functions, \( u_1, \ldots, u_m : W \to \mathbb{R} \), and in all the non trivial cases the optima for one function are distinct from the optima of the remaining ones. A key point is that not only one has to consider the optima of the individual functions, which usually are finite, but also one usually finds an infinite number of so-called non–dominated points. They are defined precisely as follows.

Definition 1 (Pareto optimality). Let \( W \) be an open subset of \( \mathbb{R}^n \), or an \( n \)-dimensional manifold, and let \( u_1, \ldots, u_m : W \to \mathbb{R} \) be smooth functions. A point \( \bar{x} \in W \) is called a non–dominated point, or a Pareto optimum, if there is no \( x \in W \) such that \( u_i(x) \geq u_i(\bar{x}) \) for all \( i = 1, \ldots, m \) and \( u_j(x) > u_j(\bar{x}) \) for some \( j \). If there exists a neighborhood \( V \subseteq W \) of \( \bar{x} \) where \( \bar{x} \) is Pareto optimum, then \( \bar{x} \) is called a local Pareto optimum.

1.2. The necessity for global representations of the Pareto sets. As pointed out for instance in [9], the set of Pareto optima is in many cases a large and complicated nonconvex set and most of the existing algorithms, being inspired by local search ideas from traditional linear and nonlinear programming, fail at giving a truly global representation of the set of Pareto optima. Also [11] stresses that “a whole
collection of Pareto optimal points, representative of the entire spectrum of efficient solutions” would be helpful in facilitating design in engineering applications.

Recent multiobjective optimization literature tackled this issue focussing on defining algorithms producing even distributions of Pareto points [11, 29, 30, 62], while an alternative philosophy [41–43, 49] dealt with producing local meshes approximating Pareto sets, relying on continuation (homotopy) strategies. In the recent paper [38], both topics are addressed. Alternative techniques aiming to approximate the entire optimal set are described in the recent papers [18, 27], in the survey [44] and in the references therein.

We want here to highlight a key feature of the Pareto set which makes it, in general nonconvex cases, a complicated set. Its complexity is even amplified when the Pareto set is viewed in the output space.

![Fig. 1.1. Possible problems arising when the objectives are nonconvex functions. (a) The Pareto set is composed by separate branches. (b) A connected global Pareto set is composed by separate local branches crossing each other.](image)

Indeed, the set of all global Pareto optima can be disconnected, i.e., composed by separate portions of seemingly smooth surfaces (see figure 1.1(a)). Furthermore, even when the image of the set of global Pareto optima is a connected set, in fact it could be composed by cutting and sewing together different locally optimal branches (see figure 1.1(b)), coming from separate zones of the domain. We will illustrate in the sequel that this kind of behavior is not an artifact obtained with unrealistic functions but in a sense represents a typical situation that is not destroyed by slight deformations of the functions. Those situations are persistent, or more technically, structurally stable.

We notice that the algorithms mentioned above are expected to work properly only in a local sense, although they are intended to capture some of the global features of the optimal set. Moreover, apart from the homotopy techniques, they are point–wise strategies, in the sense that as Pareto optimal set they produce a scatter of points; the evenness of the distribution of points is then estimated on the image space. In some applications those points are joined together in a compound structure, e.g., a Delaunay triangulation, but only a posteriori and in the output space. It should be noticed that
because of the effects of mappings described above, defining such a structure from the output space, i.e., joining nearby values of optimal points, is subject to failure: the corresponding preimage points, indeed, are not necessarily nearby, or even connected in the way suggested by the positions of their images. Conversely, the images of nearby optimal points are nearby, because of continuity.

We propose instead that a faithful global representation of the Pareto set in general nonconvex settings is obtained according to the following three steps. Firstly, by shifting the focus from the output space to the input space, secondly by approximating the full set of the local Pareto optima, and thirdly by adopting a set–wise standpoint, namely using compound geometrical objects as simplicial complexes instead of scatters of points. The first step unfolds the singularities (branches crossing, cusp points and so on) occurring as an effect of the mapping. Indeed, as illustrated in the sequel, the preimage of the Pareto set is non–singular, as it exhibits in general a regular manifold structure. The second step, because of possible superpositions of local branches, guarantees that every portion of the global Pareto optimal set is represented. Thirdly, simplicial complexes, i.e., meshes, faithfully reflect the manifold structures and explicitly offer the desired parametrization for each portion of the Pareto set, allowing to perform “trade–off studies” among the conflicting objectives. Indeed, trade–off studies may be the application of greatest practical importance of multiobjective optimization. Nevertheless, from the above discussion it is clear that trying to track the surface of the Pareto set by picking points from the output space, as point–wise strategies are aimed to do, is supposed to work correctly only for limited intervals.

There are at least two reasons why our program has not yet been pursued in its entirety. First of all, in a number of situations, the numerical techniques available in literature are able to build sufficiently faithful representations of the Pareto set. E.g., when the functions at hand are convex, or relatively simple, or when the singularities are situated far away from interesting zones, a global investigation of the problem is not required. Moreover, typically, trade studies are performed in the neighborhood of a previously determined solution, therefore they can be limited to a non problematic branch of the Pareto set giving back as well the important information. Secondly, it is clear that a global exploration of the domain is a demanding task which could be far out of the scopes of a typical design problem.

Nevertheless, faithful global representations of the Pareto set are a worthy goal to pursue, because they complement existing local exploitation strategies in two senses: they resolve the above mentioned problematic superpositions and they facilitate the location of important zones, which could merit further investigation. It is clear that this kind of program has to be implemented in an efficient way in order to be realistically useful in applications. On the other hand, even a roughly sketched global picture of the whole situation can give crucial information on the problem at hand, suggesting correctly the location of paramount zones.

1.3. Global analysis and multiobjective nonlinear programming. With this in mind, we have devised a novel numerical strategy for approximating Pareto sets, theoretically based on the global analysis framework established by S. Smale and others in the early 1970's [12,13,15,16,55,56,63–65] and in more recent work [33,34].

See [54]. For brevity, we speak a bit loosely of global analysis also when referring to concepts of singularity theory or differential topology.
ALBERTO LOVISON

Motivated by his discussions with G. Debreu\(^3\), Smale investigated the problem of optimizing several functions within the dynamical systems arena. In the series of works that followed there emerged interesting topological and geometrical features of the sets of the Pareto optima. The notion of Pareto critical set \(\theta\), generalizing the concept of critical point for scalar functions, was introduced and furthermore, local Pareto optima were characterized by means of first and second derivatives. Quoting Smale\(^5\):

“We study the local and global nature of \(\theta\), as one uses freshman calculus to study the maximum of a single function.”

One of the basic facts highlighted in Smale’s global analysis framework, is that under the assumptions of second order differentiability and some generic transversality condition, Pareto optimal sets are portions of \((m - 1)\)-dimensional manifolds. It is fundamental that a slight deformation of the functions do not alter substantially the Pareto set. Global analysis is the proper setting where to study such kind of resilience properties. A mapping \(u : W \to \mathbb{R}^m\) is said structurally stable\(^4\) if there exists a neighborhood \(N(u)\) in the \(C^r\) topology such that every function \(\tilde{u}\) in \(N(u)\) is equivalent to \(u\), i.e., there exist diffeomorphisms \(h, k\), close to the identities of the respective spaces, such that the diagram:

\[
\begin{array}{ccc}
W & \xrightarrow{u} & \mathbb{R}^m \\
\downarrow \scriptstyle{h} & & \downarrow \scriptstyle{k} \\
W & \xrightarrow{\tilde{u}} & \mathbb{R}^m
\end{array}
\]

commutes. Clearly if two mappings are equivalent, their Pareto sets are diffeomorphic. One of the main results of global analysis is that there exists an open and dense set in \(C^r(W, \mathbb{R}^m)\) of structurally stable mappings\(^5\). In other words, the Pareto set of almost every mapping \(u\) is as close as desired to the Pareto set of any other mapping in a sufficiently small neighborhood of \(u\). This is clearly of fundamental importance for the applications: when functions are known only with a certain approximation, as usual in engineering design problems, the set of optimal points is guaranteed to be approximated correctly by any convergent sequence of functions\(^{[7,54,60]}\). Moreover, a generalization of Morse theory for several functions can be defined\(^{55,63}\). The original idea of structural stability is a joint work from an engineer, A. Andronov, and a mathematician, L. Pontryagin, see\(^{53,54}\).

\(^3\) Debreu won the Nobel prize for Economics in 1983 “for having incorporated new analytical methods into economic theory and for his rigorous reformulation of the theory of general equilibrium”. For an account of the cooperation between Smale and Debreu, see\(^{[15,16]}\).

\(^4\) To be precise, we should speak of stability of mappings, while structural stability is more often used when speaking about differential equations. On the other hand we must speak about stability of Pareto optima, which is instead a concept deriving from the study of stability of equilibria, and refers to critical points which are maxima. Therefore we will keep speaking of structural stability when dealing with typical singularities of mappings.

\(^5\) It is necessary that \(m < 7\) and \(n \neq 8\), or \(m < 6\) and \(n = 8\)\(^{28}\).

\(^6\) The original idea of structural stability is a joint work from an engineer, A. Andronov, and a mathematician, L. Pontryagin, see\(^{[53,54]}\).
The algorithms of this paper can also be considered as a globalization and generalization to more than two objectives of the homotopy techniques, while the use of tessellations can be thought of as the specialization of the techniques of simplicial pivoting \cite{3,5} to the problem of optimizing several functions. A strong similarity can be found in the method proposed by \cite{49}, where the authors detect and progressively refine the hypercubes containing the Pareto sets, relying on the standard Karush–Kuhn–Tucker conditions, instead of Pareto criticality.

2. The global analysis framework. We recall now Smale’s definitions and results. Let \( W \subseteq \mathbb{R}^d \) be an open set or more generally a smooth \( n \)-dimensional manifold, \( u : W \to \mathbb{R}^m \) a smooth vector function, with \( m \leq n \). The singular set \( \Sigma \subseteq W \), is the collection of singularity points, i.e., the points where the rank of the Jacobian \( Du(x) \) is non-maximal. If \( m = 1 \), the singular set coincides with the set of critical, or stationary, points, i.e, \( Du(x) = 0 \). It can be proved that under generic conditions the singular set is a smooth manifold.

Let \( \text{Pos} \) be the open positive cone in \( \mathbb{R}^m \), \( \text{Pos} := \{ y \in \mathbb{R}^m \mid y_j > 0, \forall j = 1, \ldots, m \} \), and let \( C_x \) the corresponding open cone in the tangent space \( T_x W \), \( C_x := Du^{-1}(\text{Pos}) \).

Definition 2 (Pareto critical set \( \theta \)). The set
\[
\theta := \{ x \in W \mid C_x = \emptyset \},
\]
(2.1)
is called the Pareto critical set.

We characterize \( \theta \) in terms of the Jacobian of \( u \).

Proposition 3 (First order proposition). Let \( x \in W \). Then, \( x \in \theta \) if and only if:

(a) \( \{ Du_j(x) \}_{j=1,...,m} \) do not belong to a unique open half space of the cotangent space \( T^*_x W \).

(b) \( \exists \lambda_j \geq 0, j = 1, \ldots, m \), not all zero such that \( \sum_j \lambda_j Du_j(x) = 0 \).

Remark 4. The meaning of Proposition 3 is to exclude at the first order, for \( x \) to be critical, the existence of paths along which all the objectives \( u_j \) can be incremented at the same time. If there were an open half space containing all \( Du_j \), as in condition (a), any direction in this half space would be a direction of improvement for every \( u_j \). Equivalently, condition (b) states that the gradients \( Du_j \) should be linear dependent and furthermore should “oppose” each other. In other words, moving in the direction of maximal increasing according to one of the \( u_j \) causes one or more of the remaining \( u_i \) to strictly decrease.

Remark 5. In the bi–objective case, \( m = 2 \), Proposition 3 states that in Pareto critical points the two gradients are collinear and in opposition to each other. Also critical points for one of the two objectives are Pareto critical.

In analogy with freshman calculus, (Pareto) criticality is a necessary condition for \( x \) to be optimal. In order to discriminate the nature of the Pareto critical points we introduce a notion of stability and point out its relation with the second derivatives of \( u \). This will give sufficient conditions for \( x \) to be Pareto optimal.

Definition 6. A curve \( (a,b) \ni t \mapsto \varphi(t) \in W \) is said to be admissible if
\[
\frac{d}{dt} u_i(\varphi(t)) > 0, \quad t \in (a,b), \quad \forall i = 1, \ldots, m.
\]
(2.2)

\footnote{The case \( m < n \) is less frequent. We will consider some aspect of this case in the sequel.}
Clearly, if a point is Pareto critical, there could not exist admissible curves passing through it. In order to establish its optimality it is necessary to investigate the behavior of the admissible curves in a neighborhood of a critical point. Admissible curves are smooth paths along which every objective is incremented. Therefore, they move towards local Pareto optima; conversely, if a critical point captures all neighboring admissible curves, that point is a local Pareto optimum.

**Definition 7.** A Pareto critical point $x$ is said to be stable, $x \in \theta_S$, if, given a neighborhood $V_x$ of $x$ in $W$, there exists a neighborhood $U_x$ of $x$ in $V_x$, such that every admissible curve $\varphi : [a, b) \to W$, with $\varphi(a) \in U_x$ satisfies $\text{Image}(\varphi) \subset V_x$. Pareto stability can be fully decidable by carefully examining the second derivatives of the objectives. In the single objective case, by virtue of the Morse’s Lemma, it is possible to find a coordinate system where the objective $u$ can be written as a quadratic polynomial $u = \pm x_1^2 \pm \cdots \pm x_d^2$, which number of minus signs defines the Morse index, and therefore decides the nature of the critical point (maximum, minimum or saddle) [35]. With some effort, results can be extended to multiple objectives: second derivatives are not defined invariantly, but if we think about them as a symmetric bilinear form restricted to the kernel of the differential $Du(x)$ assuming values on the cokernel $\mathbb{R}^m/\text{Image}(Du(x))$, then this form is invariantly defined. It is called “2nd intrinsic derivative” (see [28, 40]). The restriction to the kernel of the tangent map $Du(x)$ has also the following meaning. By investigating the attractive/repulsive behavior of admissible curves in a neighborhood of a critical point, we will not be interested in what happens along the directions parallel to the critical set, while the orthogonal space will be the arena where the stability of the critical points will be decided. The case of greatest importance is where $\text{corank } Du(x) = 1$ (i.e., rank $Du(x)$ is $m - 1$). In this case the second intrinsic derivative assumes values in a 1–dimensional vector space. If we consider $x \in \theta$, we have $\text{Image}(Du(x)) \cap \text{Pos} = \emptyset$, thus $\mathbb{R}^m/\text{Image}(Du(x))$ has a canonical positive ray. We call the 2nd intrinsic derivative, in this case, the generalized Hessian $H_x$. It makes sense to say that $H_x$ is negative definite or positive definite, as well as to define an index, as the index of the symmetric form $H_x$. We set

$$\partial \theta = \left\{ x \in \theta \mid \text{Image}(Du(x)) \cap \{ \text{Cl(Pos) \ \{0\}} \neq \emptyset \right\} \quad (2.3)$$

where $\text{Cl(Pos)}$ is the closure of $\text{Pos}$.

**Proposition 8 (2nd order Proposition).** Let $u : W \to \mathbb{R}^m$ a smooth map with $x \in \theta$, $x \notin \partial \theta$ and $\text{corank } Du(x) = 1$. Then

(a) if the generalized Hessian $H_x$ is negative definite, then $x \in \theta_S$.

(b) Let $\lambda_j \geq 0$, $j = 1, \ldots, m$ be as in the 1st order proposition; then (up to a positive scalar)

$$H_x = \sum_{j=1}^{m} \lambda_j D^2u_j(x), \quad \text{on } \ker Du(x). \quad (2.4)$$

The proposition is proved in [56], while a discussion of the genericity of the hypotheses on the rank assumption is given in [55].

Most importantly, Proposition 8 offers a useful and workable criterion for deciding the stability of critical points. We will translate numerically this proposition in Algorithm 2.

2.1. The structure of Pareto sets. We start by recalling the notion of Thom’s stratification (see [58, 61]).
Definition 9. Let $A \subset W$ be a closed subset. A stratification $S$ of $A$ is a finite collection of connected submanifolds of $W$ satisfying the following properties:

1. $\bigcup_{S \in S} S = A$.
2. If $S \in S$ then $\partial S = \text{Cl}(S) \setminus S$ is a union of elements of $S$ of lower dimension.
3. If $S \in S$ and $U$ is a submanifold of $W$ transversal to $S$ at $x \in S$ then $U$ is transversal to all elements of $S$ in a neighborhood of $x$.

The following theorem has been proved in [12]. Consider the space $C^\infty(W, \mathbb{R}^m)$ endowed with the $C^\infty$ topology. $W$ is a compact manifold with dimension $n \geq m$.

Theorem 10 ($\theta$ is a stratified set of dimension $m - 1$). There is an open and dense set $G \subset C^\infty(W, \mathbb{R}^m)$ such that if $u \in G$ then $\theta$ is a stratified set of dimension $m - 1$.

Remark 11. If $m > n$, it is possible to prove that, for a generic mapping $u$, $\theta$ is a stratified set of dimension $n$.

From the point of view of the numerical applications, we state that in the generic case the strata of the Pareto critical set $\theta$ can be discretized by means of a collection of $(m - 1)$-dimensional meshes. Obviously we would like to refine this procedure to $\theta_S$. Unfortunately, the following conjecture has been proved only for $m = 2, 3$ (see [13, 63]).

Conjecture 12. There is an open and dense set $G \subset C^\infty(W, \mathbb{R}^m)$ such that if $u \in G$ then $\theta$ is a stratified set and $\theta_S$ is a union of strata.

Remark 13. The stable Pareto critical set $\theta_S$ is formed by all the local Pareto optimal points. The global Pareto optimal points cannot be distinguished from local optima by means of differential features as in the statements presented above. Global Pareto optima can only be filtered out a posteriori.

3. Numerical translation of the global analysis approach. In the following sections we illustrate numerical methods for approximating Pareto sets on the basis of Propositions 3 and 8. The procedure is reminiscent of contour plot algorithms for plotting level sets of functions, and is a special instance of general strategies for piecewise-linear approximation algorithms for implicitly defined manifolds [1, 3, 5, 6]. The method determines a simplicial complex approximating the singular set $\Sigma$ and then refines it to the critical set $\theta$ and to the stable critical set $\theta_S$. Because the strategy proposed consists in a continuation method focused on the manifold structure of Pareto optima inherited by the singular set, we coined the term singular continuation.

3.1. First order search algorithm. Algorithm 1 translates numerically Proposition 8. We start by considering a set of data points $D = \{P_1, \ldots, P_N\}$ where we will evaluate the Jacobian $J_u$, then we build a Delaunay tessellation having $D$ as nodes. We assume that the nodes $P_1, \ldots, P_n$ are in general position, i.e., they give rise to a valid Delaunay tessellation. Better results are obtained if the simplexes are “round”, i.e., they do not possess very thin or very large angles. Special tessellations, e.g., Freudenthal–Kuhn, simplify the operation of “pivoting” from a simplex to the adjacent, speeding up the process of gluing together the polytopes composing the implicitly defined manifold [5]. Hereafter, we also assume that the dataset is sufficiently dense to resolve all the feature of the singular manifold $\Sigma$. More precisely, we assume that every connected component of $\Sigma$ intersects at least one of the

---

8In the implementation considered in what follows we employed the qhull software [8], based on the computation of convex hulls, and, in the two dimensional examples, we employed the triangle software [51, 52]. For iterative schemes, a efficient alternative is offered by the Bowyer–Watson algorithm [10, 66], which is incremental.
\[(n - m)\text{-faces } \Delta \text{ of the tessellation, and the intersection is unique and transversal, i.e, } \dim T_x \Sigma \oplus T_x \Delta = n = \max.\] Doing so \(\Sigma\) is guaranteed to be homeomorphic to its piece-wise linear approximation. We denote by \(\Sigma, \theta\) and \(\theta_S\) the portions of the singular set, critical set and stable critical set, respectively, which possibly are contained in a simplex \(\Delta\) of the tessellation of the domain considered. Hatted symbols, \(\hat{\Sigma}, \hat{\theta}\) and \(\hat{\theta}_S\), denote the corresponding piecewise linear approximations. The details of the algorithm are discussed in subsection 3.2.

**Algorithm 1** First order algorithm for approximating the Pareto critical set \(\theta\)

1. Consider a set of data points \(D = \{P_1, \ldots, P_N\}\);
2. evaluate the gradients of the \(u_j\) on the data points;
3. build a Delaunay tessellation on the nodes \(D\);
4. for all Delaunay simplex \(\Delta = \langle P_{i_0}, \ldots, P_{i_n}\rangle\) in the tessellation do
5. compute the \((m - 1)\)-polytope \(\hat{\Sigma}\) where the 1st order approximation of the Jacobian of \(u\) vanishes;
6. extract the sub-polytope \(\hat{\theta}\) where the vanishing linear combination \(\lambda_1 Du_1 + \cdots + \lambda_mD u_m = 0\) has non negative coefficients;
7. end for
8. compose a simplicial complex glueing together adjacent polytopes \(\hat{\theta}\).

**Remark 14.** The algorithm assumes \(n \geq m\). When \(m > n\) things extend quite easily, because the singular set is all of the input domain, and as recalled in Section 2.1 the critical set is a stratified set. More precisely, the gradients are always linearly dependent, thus it is sufficient to skip step 5 of Algorithm 1.

### 3.2 Analysis of simplexes

We cycle through the tessellation simplexes \(\Delta = \langle P_{i_1}, \ldots, P_{i_{n+1}}\rangle\) and approximate the portion of the Pareto critical set \(\theta\) possibly contained in \(\Delta\). To determine the linear approximation \(\hat{\theta}_s\) of the stable Pareto critical portion \(\theta_s \cap \Delta\) we recall that \(\theta\) is contained in the singular set \(\Sigma\), i.e., the set where the rank of the differential \(Du(x)\) is less than maximal:

\[
\theta_s \subseteq \theta \subseteq \Sigma \subseteq W, \quad (\Rightarrow \quad \hat{\theta}_s \subseteq \hat{\theta} \subseteq \hat{\Sigma} \subseteq \Delta) \quad (3.1)
\]

Adjacent approximate portions \(\hat{\theta}_s\) are eventually sewed together.

#### 3.2.1 Singular set \(\hat{\Sigma}\)

We fix a cell \(\Delta := \langle P_1, \ldots, P_{n+1}\rangle\). The Jacobian is an \(n \times m\) matrix which rank is non maximal on the singular set \(\Sigma\). The rank of \(J_u\) drops when the rows are linearly dependent, e.g., when a suitable subset of the \(m\)-order
minors are degenerate. We consider for instance the following submatrices:

\[
M_1 = \begin{pmatrix}
\frac{\partial u_1}{\partial x_1} & \cdots & \frac{\partial u_1}{\partial x_m} \\
\vdots & \ddots & \vdots \\
\frac{\partial u_m}{\partial x_1} & \cdots & \frac{\partial u_m}{\partial x_m}
\end{pmatrix}, \quad M_2 = \begin{pmatrix}
\frac{\partial u_1}{\partial x_2} & \cdots & \frac{\partial u_1}{\partial x_{n+1}} \\
\vdots & \ddots & \vdots \\
\frac{\partial u_m}{\partial x_2} & \cdots & \frac{\partial u_m}{\partial x_{n+1}}
\end{pmatrix},
\]

... ... ...

\[
\cdots, \quad M_{n-m+1} = \begin{pmatrix}
\frac{\partial u_1}{\partial x_{n-m+1}} & \cdots & \frac{\partial u_1}{\partial x_n} \\
\vdots & \ddots & \vdots \\
\frac{\partial u_m}{\partial x_{n-m+1}} & \cdots & \frac{\partial u_m}{\partial x_n}
\end{pmatrix}.
\] (3.2)

We denote the number of minors by \( r := n - m + 1 \) and set \( \omega_j(x) := \det M_j(x) \), for \( j = 1, \ldots, r \) and consider all the \((r + 1)\)-faces of the cell \( \Delta \), i.e., for every \( \{i_1, \ldots, i_{r+1}\} \subseteq \{1, \ldots, n+1\} \), with \( i_1 < i_2 < \cdots < i_{r+1} \), we consider the simplex \( \langle P_{i_1}, \ldots, P_{i_{r+1}} \rangle \). The solution \((\mu_1, \ldots, \mu_{r+1})\) of the system:

\[
\begin{align*}
\mu_1 \omega_1(P_{i_1}) + \cdots + \mu_{r+1} \omega_1(P_{i_{r+1}}) &= 0 \\
\vdots &= \vdots \\
\mu_1 \omega_{r+1}(P_{i_1}) + \cdots + \mu_{r+1} \omega_{r+1}(P_{i_{r+1}}) &= 0 \\
\mu_1 + \cdots + \mu_{r+1} &= 1
\end{align*}
\] (3.3)

leads to a singular vertex \( Q := \mu_1 P_{i_1} + \cdots + \mu_{r+1} P_{i_{r+1}} \) of \( \tilde{\Sigma} \) if all \( \mu_j > 0 \), i.e., if \( Q \) is contained in the \((r + 1)\)-face of \( \Delta \) considered.

The (possibly empty) singular set \( \tilde{\Sigma} \) is an \((m - 1)\)-polytope defined as the convex hull of the singular vertices \( Q \).

3.2.2. Critical set \( \tilde{\theta} \). In the previous subsection we have detected the singular set \( \Sigma \), on the basis of the fact that on the singular set the gradients are linearly dependent. On the other hand, on the critical set \( \theta \) there exists a positive linear combination of the gradients giving zero. Thus we proceed by estimating the coefficients \( \lambda_j \) of the vanishing linear convex combination of the gradients, and cutting out the critical set \( \theta \) from \( \Sigma \) by intersection with the half spaces where the linear interpolations of the \( \lambda \)'s are positive.

More precisely, we solve the system:

\[
\begin{align*}
\lambda_1 Du_1(P) + \cdots + \lambda_m Du_m(P) &= 0, \\
\lambda_1 + \cdots + \lambda_m &= 1
\end{align*}
\] (3.4)

for \( \lambda_1, \ldots, \lambda_m \). The Jacobian of \( u \) has rank \( m - 1 \) in almost all the points of the singular set (generic hypothesis), thus the system (3.4) has rank \( m \), and by the implicit function theorem \( \lambda_j \) are smooth functions of \( P \). As a result the level sets \( \{ \lambda_j(P) = 0 \} \), which define the boundary of \( \theta \), are smooth manifolds. At the first order we are working with, the requests \( \lambda_j(P) \geq 0 \) cut out half spaces in \( \tilde{\Sigma} \), defining possibly a critical sub polytope \( \tilde{\theta} \) in \( \Delta \).

We notice that we do not know the actual values of \( Du \) on the singular vertices, i.e., the nodes of \( \tilde{\Sigma} \). Nevertheless, we can estimate them by linearly interpolating...
the values of $Du$ on the data nodes $P_{i_1}, \ldots, P_{i_{r+1}}$ defining the vertex $Q$ in $\hat{\Sigma}$. By taking the coefficients $\mu_1, \ldots, \mu_{r+1}$ solving the system [3.3], we are guaranteed that the $\tilde{Du}_j(Q) := \mu_1 Du_j(P_{i_1}) + \cdots + \mu_{r+1} Du_j(P_{i_{r+1}})$ are linearly dependent, and we are justified in solving for the vanishing linear combination $\lambda_1 \tilde{Du}_1(Q) + \cdots + \lambda_m \tilde{Du}_m(Q) = 0$.

3.3. Convergence analysis for $\theta$. Let us consider for this section a single simplex $\Delta$. Intuitively, it is clear that the approximation $\hat{\Sigma}$ of $\Sigma$ obtained by linear interpolation is quadratically good because of Taylor’s theorem. We state more precisely this result in the set–wise context we have adopted. The distance between the sets $A$ and $B$ can be measured in terms of Hausdorff distance:

$$d_H(A, B) := \max \left( \sup_{x \in A} \inf_{y \in B} d(x, y), \sup_{y \in B} \inf_{x \in A} d(x, y) \right).$$

(3.5)

**THEOREM 15** (Quadratic precision for $\Sigma$). Let $P_0, \ldots, P_n$ be in general position, and such that $Du$ has maximum rank. We denote by $\Delta = \langle P_0, \ldots, P_n \rangle$ the $n$–simplex which vertices are those points. Let $\omega_1(x), \ldots, \omega_r(x)$ a selection of independent minors of $Du$, and $\hat{\omega}_j(x)$ the 1st order interpolation of the values of $\omega_j$ on the nodes $P_i$. Assume $0$ is a regular value for $\omega_1, \ldots, \omega_r$, that the zero levels of the $\omega_j$ are transversal and that $\omega_j(P_i) \neq 0$, for all $i, j$. Then

$$\Sigma = \{ \omega_1(x) = 0 \} \cap \cdots \cap \{ \omega_r(x) = 0 \},$$

(3.6)

$$\hat{\Sigma} = \{ \hat{\omega}_1(x) = 0 \} \cap \cdots \cap \{ \hat{\omega}_r(x) = 0 \},$$

(3.7)

and there exists a constant $C$:

$$d_H(\Sigma, \hat{\Sigma}) \leq C\delta^2,$$

(3.8)

where $\delta > 0$ is the diameter of the simplex $\Delta$.

**Proof.** First of all, we notice that the $\omega_k(x)$ are polynomials of the first derivatives of $u$, thus they are smooth in our hypotheses. Inductively, consider $r = 1$ and denote $\omega = \omega_1$. By Taylor’s theorem,

$$\omega(x) = \hat{\omega}(x) + O \left( |x - P_0|^2 \right), \quad \text{i.e.,}$$

$$|\omega(x) - \hat{\omega}(x)| \leq C\delta^2,$$

(3.9)

for a suitable $C > 0$. Assume, without loss of generality, $\omega > 0$ on $P_0, \ldots, P_k$ and $\omega < 0$ on $P_{k+1}, \ldots, P_N$. Let $\varepsilon := C\delta^2$. (See panel (a) of Figure [3.1].) Thus the zero levels of $\omega$ and $\hat{\omega}$ are comprised between the $\pm \varepsilon$ levels of $\hat{\omega}$, i.e.,

$$\left\{ x \in \Delta \mid \omega(x) = 0 \right\} \subseteq \left\{ x \in \Delta \mid -\varepsilon \leq \hat{\omega}(x) \leq \varepsilon \right\}.$$

(3.10)

By the compactness of $\Delta$, there exist $x_0 \in \{ \hat{\omega} = 0 \}$, $x_\varepsilon \in \{ \hat{\omega} = \varepsilon \}$, such that,

$$d_H(\{ \hat{\omega} = 0 \} \cup \{ \hat{\omega} = \varepsilon \}) = |x_0 - x_\varepsilon|$$

(3.11)

---

\(^{10}\) General estimates on the accuracy of piecewise–linear approximations of implicitly defined manifolds are proved in [2].
and it holds that

$$
\tilde{\omega}(x_\varepsilon) - \tilde{\omega}(x_0) = \left| \tilde{\omega}'(x_0) \cdot (x_\varepsilon - x_0) \right| = \left| \frac{\partial \tilde{\omega}}{\partial w}(x_0) \right| |x_\varepsilon - x_0|, \quad (3.12)
$$

where $w = \frac{x_{\varepsilon} - x_0}{|x_{\varepsilon} - x_0|}$. By means of an elementary linear algebra argument we have also that

$$
\left| \frac{\partial \omega}{\partial w}(x_0) \right| \geq \min_{i=1, \ldots, k, \quad i' = k+1, \ldots, n} \left| \frac{\tilde{\omega}(P_i) - \tilde{\omega}(P_{i'})}{P_i - P_{i'}} \right| =: B > 0, \quad (3.13)
$$

so we can conclude

$$
|x_0 - x_\varepsilon| \leq \frac{\varepsilon}{B} = \frac{C}{B} \delta^2 = C \delta^2 \quad (3.14)
$$

and eventually

$$
d_H(\{\omega = 0\}, \{\tilde{\omega} = 0\}) \leq C \delta^2. \quad (3.15)
$$

Consider now $r > 1$, and assume inductively that the Hausdorff distance between the intersection of the zero levels of $r - 1$ transversal functions and the intersection of the zero level of the respective linear interpolations on an $n$–simplex is quadratically smaller than the simplex diameter. Thus we have

$$
\Sigma_- = \{\omega_1(x) = 0\} \cap \cdots \cap \{\omega_{r-1}(x) = 0\}, \quad (3.16)
$$

$$
\tilde{\Sigma}_- = \{\tilde{\omega}_1(x) = 0\} \cap \cdots \cap \{\tilde{\omega}_{r-1}(x) = 0\}, \quad (3.17)
$$

$$
d_H(\Sigma_-, \tilde{\Sigma}_-) \leq C \delta^2. \quad (3.18)
$$

If we consider one more function $\omega_r(x)$ on the linear space $\tilde{\Sigma}_-$, we are in the previous case, so there exists $A > 0$,

$$
d_H(\tilde{\Sigma}_- \cap \{\omega_r(x) = 0\}, \tilde{\Sigma}_- \cap \{\tilde{\omega}_r(x) = 0\}) \leq A \delta^2. \quad (3.19)
$$
By transversality of the $\omega_1, \ldots, \omega_r$, the fact holding for the linear space $\hat{\Sigma}_-$ holds also for the compact manifold with boundary $\Sigma_-$ and the function $\omega_r$ (see Lemma 16 for the details). Thus there exists a $B > 0$ such that
\[ d_H (\Sigma_- \cap \{ \omega_r(x) = 0 \}, \Sigma_- \cap \{ \hat{\omega}_r(x) = 0 \}) \leq B \delta^2. \] (3.20)

On the other hand, for the intersection of the zero levels of the transversal functions $\omega_1, \ldots, \omega_{r-1}$ on the linear space $\{ \hat{\omega}_r(x) = 0 \}$, by the inductive hypothesis there exists $C > 0$
\[ d_H (\{ \omega_{r}(x) = 0 \} \cap \Sigma_-, \{ \omega_{r}(x) = 0 \} \cap \hat{\Sigma}_-) \leq C \delta^2, \] (3.21)
so the thesis is proved by the triangle inequality.

**Lemma 16.** Let $\Sigma$ a manifold with boundary diffeomorphic to an $n$–simplex $\Delta$, and $\omega : \Sigma \to \mathbb{R}$ differentiable and without critical points inside $\Sigma$. We have $\omega(x) = \hat{\omega}(x) + O(\delta^2)$, where $\hat{\omega}$ is an affine approximation and $\delta$ is the simplex diameter. Thus we have that
\[ d_H (\{ \omega(x) = c \}, \{ \hat{\omega}(x) = c \}) \leq C \delta^2, \quad \text{for all } c \in \mathbb{R}. \] (3.22)

**Proof.** Let $\varphi : \Delta \to \Sigma$ be a diffeomorphism, with $\xi > |\varphi'| > \eta > 0$. Thus we have, for all $y \in \Delta$,
\[ \omega \circ \varphi(y) = \hat{\omega} \circ \varphi(y) + O(\delta^2). \]
For any $y^*$ in the zero level of $\omega \circ \varphi$ we can find a line segment $[y_1, y_2]$, with $y_1$ being one of the nodes of $\Delta$ where $\omega \circ \varphi$ is negative and $y_2$ is a point on a face of $\Delta$ where on the forming nodes $\omega \circ \varphi$ is positive. By continuity there exists a point $\hat{y}$ on the line $[y_1, y_2]$ where $\hat{\omega} \circ \varphi$ is zero.
Thus
\[ \omega \circ \varphi(y^*) - \omega \circ \varphi(\hat{y}) = \hat{\omega} \circ \varphi(y^*) - \hat{\omega} \circ \varphi(\hat{y}) + O(\delta^2) = \hat{\omega}' \circ \frac{\partial \varphi}{\partial w} |y^* - \hat{y}| + O(\delta^2), \] (3.23)
which gives
\[ |y^* - \hat{y}| \leq C \delta^2. \] (3.24)

**Note 17.** The hypotheses of Theorem 15 are generic in the sense that they hold for a open and dense set of functions. In particular, $0$ is assumed to be a regular value for $\omega_1, \ldots, \omega_r$ because the set of the singular values has zero measure (Sard’s Theorem). See [7, 19, 26, 28, 31].

**Theorem 18.** In the simplex $\Delta = (P_0, \ldots, P_n)$, if $\theta$ is the Pareto critical set and $\hat{\theta}$ is its linear approximation, there exists $C > 0$ such that
\[ d_H (\theta, \hat{\theta}) \leq C \delta^2. \] (3.25)

**Proof.** The $\lambda_j$ computed as described in Algorithm 1 are first order approximations to smooth functions, apart from a measure zero set of points. Thus the conclusions of Theorem 15 apply as well to the intersection of $\Sigma$ with the half spaces $\lambda_j(P) \geq 0$. \[\square\]
3.4. Second order algorithm. In Algorithm 2 we describe how to extract the stable critical set $\theta_s$, i.e., the set of locally Pareto optimal points, from the critical set $\theta$ determined in the first order algorithm 1.

**Algorithm 2** Second order algorithm for the stable Pareto critical set $\theta_s$

1. Consider a set of data points $\mathcal{D} = \{P_1, \ldots, P_N\}$ and proceed as in Algorithm 1.
2. for all Delaunay simplex $\Delta = \langle P_{i_0}, \ldots, P_{i_n} \rangle$ in the tessellation do
3. Compute the matrix of the second derivatives $D^2 u$ on the nodes $P_{i_0}, \ldots, P_{i_n}$
4. On the vertices $Q$ of $\hat{\theta}$, linearly interpolate the second derivatives $\hat{D}^2 u(Q)$
5. Compute a basis $w_1, \ldots, w_{n-m+1}$ for $\ker Du(Q)$, and set $\hat{H}(Q) := w^\top \cdot \left( \lambda_1(Q) \hat{D}^2 u_1(Q) + \cdots + \lambda_m(Q) \hat{D}^2 u_m(Q) \right) \cdot w$.
6. Compute the eigenvalues $\sigma_1, \ldots, \sigma_{n-m+1}$ of $\hat{H}(Q)$.
7. Cut out from $\hat{\theta}$ the sub polytope $\hat{\theta}_s$ where $\sigma_k \leq 0$ for all $k = 1, \ldots, n-m+1$
8. end for
9. Compose a simplicial complex glueing together adjacent polytopes $\hat{\theta}_s$

The second derivatives could be also approximated computing the finite differences of the values of the gradients on the nodes of the $n$–simplex. Indeed, setting $v_i = P_i - P_0$, $i = 1, \ldots, n$, we have

$$D^2 u = \left( \frac{\partial^2 u}{\partial x_i \partial x_j} \right)_{i,j} = \sum_k \frac{\partial^2 u}{\partial v_k \partial x_j} \cdot \frac{\partial v_k}{\partial x_i} \simeq \sum_k (\nabla u(P_k) - \nabla u(P_0))_j \cdot (P_k - P_0)_i.$$  

(3.26)

Using this formula, the quadratic precision cannot be guaranteed for locating boundary points of the stable critical set. Furthermore, because the boundary faces belong to different simplexes, the estimated boundary points for $\theta_s$ would jump from simplex to simplex.

On the other hand, the formula will be correct for discriminating the nature of inner stable critical points, without extra computations. Boundary simplexes can thus analyzed with second derivatives, allowing the computation of the boundary of $\hat{\theta}_s$.

4. Applications.

4.1. Two functions in two dimensional examples. A series of examples in two dimensions is presented below. Via global analysis one sees that, for structurally stable mappings, the Pareto critical set is a 1–dimensional manifold with boundary contained in $\Sigma$. Critical points can only be of one of the following types:

1. **fold**, i.e., the mapping is locally equivalent to $u_1 = x_1$, $u_2 = x_2^2$.
2. **cusp**, i.e., the mapping is locally equivalent to $u_1 = x_1$, $u_2 = x_1 x_2 - \frac{1}{3} x_3^2$.

Therefore, the branches of Pareto critical points are composed by folds, which intersect only pair–wise and at non–zero angles. Some local branches terminate in cusps, where the status of critical points can change from stable to unstable. Finally, images of folds and cusps do not intersect.

Functions gradients are evaluated on a grid of regular triangles and the critical set $\theta$ is estimated according to the first order algorithm. Boundary points are marked with black diamonds. The generalized Hessian is estimated on the nodes of the critical
Example 1. Consider two negative definite quadratic polynomials. The critical stable set is a curve joining the two individual critical points. Other singular branches occur in outer regions of the domain.

\[
\begin{align*}
    u_1(x,y) & = -1.05x^2 - 0.98y^2, \\
    u_2(x,y) & = -0.99(x - 3)^2 - 1.03(y - 2.5)^2.
\end{align*}
\] (4.1)

See Figure 4.1.

Example 2. This example is taken from [56].

\[
\begin{align*}
    u_1(x,y) & = -y, \\
    u_2(x,y) & = \frac{y - x^3}{x + 1}.
\end{align*}
\] (4.2)

The critical set is a single curve split in a stable and an unstable branch, while the separating point is a cusp. See Figure 4.2.

Example 3. In the following mapping there are two second order polynomials, one negative definite and the other indefinite. The outcome is an (unbounded) global Pareto front and a local unbounded front terminating in a cusp.

\[
\begin{align*}
    u_1(x,y) & = -x^2 - y^2, \\
    u_2(x,y) & = -(x - 6)^2 + (y + 0.3)^2,
\end{align*}
\] (4.3)

See Figure 4.3.

Example 4. The following mapping is composed by a quadratic polynomial and a bimodal function. The resulting singular set is composed by an unbounded branch and two loops. One of the loops is critical and forms a local Pareto front delimited by two
Fig. 4.2. Example 2. Red line: stable critical set. Orange line: unstable critical set.

Fig. 4.3. Example 3.

cusps, while the other loop is non critical.

\begin{align}
  u_1(x, y) &= -x^2 - y^2 - 4(\exp(-(x + 2)^2 - y^2) + \exp(-(x - 2)^2 - y^2)), \\
  u_2(x, y) &= -(x - 6)^2 - (y + 0.5)^2.
\end{align}

See Figure 4.3.

4.2. Higher input dimension. Example 5. The following mapping demonstrates the capabilities of the method in distinguishing local and global features of the
Pareto set. A widespread optimal branch is surpassed by a local branch. The sharper branch is composed by an unstable part (orange) and a stable part (red) which is interrupted by noncritical insertions (gray). Nevertheless, as illustrated in figures 4.5(a–b) the two separate branches are properly recognized by the algorithm and moreover the transitions among critical/non critical and stable/unstable intervals are detected. For comparison, the outcome of the application of a commercial implementation of normal boundary intersection by Das and Dennis [11] is shown in figures 4.5(c–d). The starting grid (green dots) was $10 \times 20 \times 10$, and we considered 50 NBI subproblems. The sequence of NBI points is marked by black stars. For this particular problem, NBI tracks correctly the broad Pareto optimal branch, in the sense that it produces a parametrization of it. However, the smaller branch is missed, although some of the points of the starting grid were close to this critical zone. It is clear that point–wise strategies suffer at tracking the Pareto optimal set and fail at performing widespread trade studies, apart from small intervals where different fronts are far apart and do

\[11\] Applications of modeFRONTIER® are a courtesy by E. Rigoni at ESTECO
not change status (from critical to non-critical, stable to unstable, and so on).

\[ p_0 = (0.0, 0.15, 0.0)^\top, \]
\[ p_1 = (0.0, -1.1, 0.0)^\top, \]
\[ M = \begin{pmatrix} -1.0 & -0.03 & 0.011 \\ -0.03 & -1. & 0.07 \\ 0.011 & 0.07 & -1.01 \end{pmatrix}, \]
\[ g(x, y, z, M, p, \sigma) = \sqrt{\frac{2\pi}{\sigma}} e^{\left(\frac{(x,y,z)^\top - M(x,y,z)^\top}{\sigma^2}\right)}, \quad (4.5) \]
\[ f(x, y, z) = g(x, y, z, M, p_0, 0.35) + g(x, y, 0.5z, M, p_1, 3.0), \]
\[ u_1(x, y, z) = \frac{\sqrt{2}}{2} x + \frac{\sqrt{2}}{2} f(x, y, z), \]
\[ u_2(x, y, z) = -\frac{\sqrt{2}}{2} x + \frac{\sqrt{2}}{2} f(x, y, z). \]

**Example 6.** The following 6 dimensional example is a regularization of the third of the ZDT problems [14], which has degenerate second derivatives. The Pareto fronts of original and modified problems correspond each other in output space. We used a Delaunay tessellation defined on 300 randomly generated points. The results are presented in figure 4.6. Critical and merely singular branches are correctly represented. Note that the critical branches are correctly marked as unstable, being minima.

\[ u_1(x_1, \ldots, x_6) = x_1, \]
\[ u_2(x_1, \ldots, x_6) = 1 - \sqrt{x_1} - x_1 \sin(10\pi x_1) + x_2^2 + \cdots + x_6^2, \quad (4.6) \]
\[ x_1 \in [0.1, 0.425], \quad x_2, \ldots, x_6 \in [-0.16, 0.16]. \]

**4.3. Three functions examples.** Example 7. The simplest nontrivial non degenerate example we can build in the three dimensional case is composed by three negative definite 2nd order polynomial functions \( f_j(x), j = 1, 2, 3 \). Additionally, we introduce a small non polynomial perturbation.

\[ f_j(x) = (x - C_j)^\top \cdot \begin{pmatrix} -\alpha_{j,1} & 0 & 0 \\ 0 & -\alpha_{j,2} & 0 \\ 0 & 0 & -\alpha_{j,3} \end{pmatrix} \cdot (x - C_j), \quad j = 1, 2, 3, \]
\[ \begin{pmatrix} u_1(x) \\ u_2(x) \\ u_3(x) \end{pmatrix} := \begin{pmatrix} f_1(x) \\ f_2(x) \\ f_3(x) \end{pmatrix} + \begin{pmatrix} 0 \\ \beta_2 \sin\left(\frac{x_2}{\gamma_2}(x + y)\right) \\ \beta_3 \cos\left(\frac{x_2}{\gamma_3}(x - y)\right) \end{pmatrix}. \quad (4.7) \]

Where \( x = (x_1, x_2, x_3)^\top \in \mathbb{R}^3 \), \( \alpha_{j,i} > 0, i, j = 1, 2, 3 \), \( C_1, C_2, C_3 \in \mathbb{R}^3 \) are distinct, non collinear points, while \( \beta_j, \gamma_j \) are real numbers. In the generic case the singular set is an hypersurface of \( \mathbb{R}^3 \), while the critical set \( \theta \), which is stable, is diffeomorphic to a triangle, i.e., \( \theta \) is a compact connected manifold with boundary and three corners, corresponding to the minima of the three functions \( u_1, u_2, u_3 \). See Figure 4.7(a).
Fig. 4.5. Example 5. Panel (a): singular (gray), Pareto critical (orange) and Pareto stable (red) sets in the problem domain. Green dots mark the nodes of the starting regular grid defining the tessellation. Octahedrons mark points separating critical and non critical branches. Spheres separate stable from unstable branches, i.e., mark cusps. Panel (b): image of singular and Pareto sets. Diamonds separate critical from non critical branches while stars mark the cusps. Panel (c)–(d): results obtained running the commercial implementation of NBI–AFSQP available in modeFRONTIER®, courtesy of E. Rigoni. Small green points are a starting regular grid, while marked points are the solutions of the 50 NBI subproblems.

Example 8. We break the convexity of the previous example by adding a secondary maximum to the first function. We define a further negative definite, 2nd order polynomial \( f_4(x) \) and set \( u(x) \) as:

\[
\begin{pmatrix}
  u_1(x) \\
  u_2(x) \\
  u_3(x)
\end{pmatrix}
:=
\begin{pmatrix}
  f_1(x) \\
  f_2(x) \\
  f_3(x)
\end{pmatrix}
+
\begin{pmatrix}
  \beta_1 \exp \left( \frac{1}{\gamma_1} f_4(x) \right) \\
  \beta_2 \sin \left( \frac{\pi}{\gamma_2} (x + y) \right) \\
  \beta_3 \cos \left( \frac{\pi}{\gamma_3} (x - y) \right)
\end{pmatrix}.
\] (4.8)
GLOBAL ANALYSIS AND MULTIOBJECTIVE OPTIMIZATION

Fig. 4.6. Example 6. Panel (a): image of the singular (gray), Pareto critical (orange) sets for regularized ZDT3. Green dots mark the nodes of the starting random distribution of points defining the tessellation.

Fig. 4.7. (a): critical set $\theta$ of example 7, (b): critical set $\theta$ of example 8.

The main portion of the Pareto set is slightly deformed while a new branch appears. In Figure 4.7(b) is shown the resulting Pareto critical set $\theta$ obtained by iterative application of Algorithm 1 as described in section 5.

4.4. A constrained example. We briefly sketch here an adaptation of Algorithm 1 to the case of equality constraints. Next we illustrate a simple application. Let $W := \{ x \in \mathbb{R}^n \mid g(x) = 0 \}$, where $g : \mathbb{R}^n \rightarrow \mathbb{R}^{n-d}$ is a smooth function such that $\partial g \big|_W$ has maximum rank.
Algorithm 3 Equality constraint case for the 1st order algorithm

1: Determine a piecewise linear approximation \( \hat{W} \) of \( W \), with nodes \( P_1, \ldots, P_n \)
2: for all simplex \( \Delta \) in the tessellation \( \hat{W} \), do
3: determine a piecewise linear approximation of the singular, critical and stable sets possibly crossing the simplex. This is done on the basis of the projections of the gradients of the \( u_j \)'s on the tangent space to \( W \). In principle, a basis for \( TW \) should be chosen respecting the orientation.
4: for all Node \( P \) of the simplex \( \Delta \) do
5: compute \( Dg(P) \) and project \( u_j(P) \) on \( \ker Dg(P) \) via \( \pi_{Dg(P)} \),
6: compute an independent set of minors for the matrix \( (\pi \text{grad } u_1(P), \ldots, \pi \text{grad } u_n(P)) \) or, equivalently,
7: compute an independent set of minors for the matrix \( (\text{grad } g_1, \ldots, \text{grad } g_{n-d}, \text{grad } u_1, \ldots, \text{grad } u_m) \)
8: end for
9: determine if all minors vanish inside the simplex \( S \), and in that case locate \( \hat{\Sigma} \) via inverse linear interpolation
10: estimate \( \lambda_j \) and determine the critical set \( \hat{\theta} \) as in Algorithm 1
11: end for
12: eventually glue together adjacent portions of \( \hat{\Sigma} \) and \( \hat{\theta} \).

Example 9. Maybe the simplest case of constrained problem is when \( W = S^2 \) and the objectives are the first two coordinates, \( u_1(x_1, x_2, x_3) := x_1, u_2(x_1, x_2, x_3) := x_2 \). Explicit algebraic computation give that the singular set \( \Sigma \) is the equator of the sphere, where the two curvilinear segments where \( x_1 x_2 > 0 \) are the critical set \( \theta \), as illustrated in figure 4.8(a). By applying algorithm 3 we start by approximating the sphere by an icosahedron. At every node \( P = (x_1, x_2, x_3), \frac{1}{2} (x_1^2 + x_2^2 + x_3^2) - 1 = 0 \), we have \( Dg(P) = (x_1, x_2, x_3) \), therefore the projections of the gradients of \( u_j \) are \( (1 - x_1^2, -x_1 x_2, -x_1 x_3) \) and \( (-x_1 x_2, 1 - x_2^2, -x_1 x_3) \). The singular set \( \Sigma \) passes through the triangles where the pair of vectors \( \pi \text{grad } u_1 \) and \( \pi \text{grad } u_2 \) change orientation in the tangent plane to \( S^2 \). It is equivalent then to compute the determinant of the matrix which columns are \( \pi \text{grad } g_j \), \( \pi \text{grad } u_1 \) and \( \pi \text{grad } u_2 \) and to determine the line along which it vanishes. This gives exactly the “equator” of the icosahedron. The signs of the \( \lambda_j \) depend on the sign of the scalar product among \( \pi \text{grad } u_j \), again giving as turning points the intersections with the axes. The results are summarized in figures 4.8(a) and (b).

5. Iterative schemes. The previously presented approach defines an approximation of the Pareto optimal set given any distribution of points in the domain. Here we propose and discuss an iterative scheme. At every step a selection of points from the approximated Pareto optimal set is added to the dataset \( D \), the gradients in the new points are evaluated, the tessellation is updated and a refined approximation of the Pareto set is built. The desired effect is obviously to get closer and closer to the actual optimal set, but an efficient strategy should produce an as uniform as possible discretization of the optimal set.

A naive approach would suggest to insert in the set of the candidates for evaluation all of the nodes of the complexes, i.e., all the stable admissible vertices computed and all of the boundary points, both for criticality and stability. Nevertheless, a glance at

\footnote{This example is also discussed in [12].}
the examples of the previous section reveals that the sizes of the optimal complexes cover a wide distribution, in particular the patches result very small if Σ passes close to tessellation nodes. Moreover, little experience shows that large patches are reduced sensibly slowly if none of their internal points is introduced. With this criteria in mind we introduce an iterative scheme for the case of two functions.

5.1. Two functions iterative scheme. In the two functions case the Pareto optimal set is a one dimensional manifold with boundary, i.e., a collection of curved intervals. The discrete approximation is a collection of polygonal curves. For every interval a sequence of candidate points equally spaced along the polygonal curve is extracted. The number of points is chosen equal to the number of segments, so that approximately every triangle containing optimal points is split as close as possible to the optimal set.

5.2. Higher number of functions. It seems reasonable to take into account of the stratified structure of θ in the design of an iterative strategy. In fact, strata should be filled as uniformly as possible, where the uniformity is determined according to the k-dimensional measure, if k is the dimension of the stratum. So, taking for instance the situation of example 7, corners’ approximations are re-evaluated at each iteration, uniformly spaced points are taken along boundary lines, exactly as in the two functions case, while internal points should be distributed proportionally to the area of the triangles and polygons composing θ. This is more difficult to be defined precisely. Indeed, the problem of uniformly filling a general n-dimensional region is a long-time crucial issue for statistical applications [46]. Furthermore, in our problem we have to fill uniformly a general n-dimensional manifold, thus we have somehow to take into account of the effects of the curvature on the measure of the volumes.

Taking inspiration from a Design of Experiments strategy called maximin distance
Algorithm 4 Uniformly filling a simplicial complex

1: Tessellate in simplexes the polytopes of the mesh
2: Build the adjacency lists of the simplexes
3: Evaluate the volume of each simplex
4: For every simplex define the accumulated volume as the sum of its volume and
the volume of the adjacent simplexes
5: Pick the simplex with the maximum accumulated volume
6: Add to the candidates stack the center of mass of this maximal simplex
7: repeat
8: Recompute the accumulated volumes excluding the already picked simplexes
9: until the desired number of candidate points is collected

We proceed as described in Algorithm 4. This algorithm, because of point 6, can lead to long and thin simplexes and to numerical instabilities when iterated many times. This problem can be tackled by the application of mesh improvement strategies, as described below for the case of two dimensional domains. However, to the author’s knowledge, general dimension mesh improvement strategies are still not available at present.

5.3. Stopping criteria. Analogously to gradient based methods of single function optimization (nonlinear conjugate gradient, Newton and Newton–like methods), a stopping criterion could be based on the magnitude of the minors $M_1, \ldots, M_r$ computed in the points of the last iteration. The magnitude of the minors is analogous to the magnitude of the gradients for single objective optimization.

In fact, we could define a different iterative strategy taking the rule of subdividing only stable critical triangles contained in simplexes where the minors are larger than a prescribed threshold.

5.4. Application. We show the behavior of the iterative scheme described above applied to the mapping in Example 4. At each iteration we generate a number of evenly spaced points along the approximate stable Pareto critical set. In order to exhibit the claimed quadratic convergence, it is necessary to sample the approximated optimal set by quadratically finer intervals, i.e., comparable to the precision gained. As a result the density of points will grow exponentially w.r.t. the number of iterations. Such a density of points rapidly deteriorates the mesh quality, i.e., skinny triangles suddenly appear leading to numerical instability. Thus, at each iteration, a number of extra nodes (namely, the circumcenters of the most skinny triangles) should be introduced in the mesh in order to produce a nicely grading. At this extent we have coupled our method with Ruppert’s algorithm, as implemented in the triangular mesh refinement software TRAINGLE by J. R. Shewchuk.

Already at the fifth iteration the triangulation starts to suffer from numerical instability, thus we consider $\hat{\theta}_S^{(4)}$ generated at the fourth iteration as the optimum and evaluate the Hausdorff distances between $\hat{\theta}_S^{(i)}$ and $\hat{\theta}_S^{(4)}$, for $i = 1, \ldots, 3$. As in can be seen in Figure 5.2 panel (a), the Hausdorff distances between the approximated Pareto sets and the numerical optimum converges superlinearly. For reference also the convergence behavior of the maximum and the mean minors magnitude are reported.

In Figure 5.1 is illustrated how the triangulation and the representation of the Pareto set evolves from one iteration to the subsequent.

In Figure 5.3 the three dimensional problem of Example 7 is tackled by the
procedure described in Algorithm 4. The algorithm has been applied by introducing only a small number (∼10) of new points on the sites with the largest magnitude of the minors. In such a way it was possible to iterate 70 times the scheme reaching a very small magnitude for the minors.

Because of the mentioned exponentially growing number of samples necessary to exhibit quadratic convergence speed for the iterative scheme, the experiment described for the two dimensional case becomes prohibitive in three dimensions.

On the other hand, a superlinear precision can be verified as well by means of a sequence of approximations obtained from a progressively finer regular meshes, corresponding to a sequence of mesh sizes \( s = 2.8, \ldots, 0.4 \). Because the Hausdorff distance among the first \( s \)-approximation and the optimal set is already comparable to the largest mesh size of the optimal set, we analyze the sequence of average distances between a point of one set from the triangles of the other set, instead of considering the maximum distances. These average distances decrease faster than linearly as it can be seen by plotting the ratio of distances and mesh sizes versus the mesh sizes, as reported in Figure 5.2 panel (b).

6. Conclusions and perspectives. We have presented a novel multiobjective optimization method which exploits the manifold structure underlying the set of Pareto optimal points. Global analysis seems the proper setting where those structures arise and can be studied. We approximate Pareto sets via simplicial complexes, specializing simplicial pivoting techniques for detecting the singular manifold \( \Sigma \) and successively cutting out critical and stable subsets \( \theta \) and \( \theta_S \). By contrast, most of the available strategies are aimed at producing a scatter of optimal points which images should be evenly distributed. We have illustrated some generic situation where this program could not be successfully completed via such point–wise strategies, because of nonconvexities of the functions. Adopting the Hausdorff measure, Newton–type estimates lead to quadratic convergence in a set–wise sense.

Because of its global character, the method proposed here is demanding. Delaunay tessellations, in particular, are defined for every possible input dimension, but are numerically workable only for small dimensional cases. The theory of singularities of mappings also highlights further limitations encountered when dealing with a large number of functions. Lastly, we have everywhere assumed the differentiability of the functions. Therefore the method is not suitable for non–smooth optimization, instead it is supposed to be applicable also via smooth surrogate functions, when approximations are consistent with the functions at hand. Possible extensions of the algorithms described in this paper are conditioned by the issues enumerated below.

6.1. The curse of dimensionality. The first problem one encounters when trying to apply this algorithms to industrial strength problems is the limitations to the input dimension. The whole procedure is based on a Delaunay tessellation of the input domain, which complexity grows exponentially with dimension. As pointed out for instance in the \texttt{qhull} documentation [8], building the convex hull of a 9-hypercube is computationally exhaustive. Analogous limitations are encountered in global optimization, where the search for optima in high dimensional domains cannot realistically be performed on real case problems. Indeed, typically, global search algorithms are rarely tested and compared over dimensions larger than 5 (see [21, 23, 39, 48, 50, 68]. This problem is structural and cannot be resolved by augmenting
Step 1. 29 pts (from 66)

Step 2. 56 pts (from 95)

Step 3. 302 pts (from 168)

Step 4. 2977 pts (from 594)

Fig. 5.1. Iterative scheme for the mapping in Example 4.
the computational resources. Therefore, the presented algorithms are best suited for low dimensional problems. In fact, the curse of dimensionality is a strong motivation for reflecting carefully on the necessity of introducing extra input variables when tackling new problems and designing experiments. A possible exit strategy could be screening the input variables [47, 57]. This practice can be surprisingly successful, because usually sparsity of effects occurs, revealing a pronounced hierarchy among input variables, leading to sensible simplification of the problem formulation.

Alternatively, as described in the recent paper [6], it is possible to redefine any problem in n-dimensional space in an equivalent problem in a linear subspace of dimension $2(m - 1) + 1$, if $m$ is the number of objectives. This is because the singular set is an $(m - 1)$-manifold, and by Whitney’s embedding theorem, in the compact case, almost all projections on linear $2(m - 1) + 1$ dimensional subspaces are diffeomorphisms. This would mean that bi-objective problems could be equivalently discussed in a 3 dimensional domain, 3 objectives would require only 5 input variables, and so on. This would dramatically reduce the computational burden of the tessellations involved.

---

13The sparsity of effects is an empirical law stating that in a generic physical experiment one usually observes that the 80% of the effects are due to the 20% of the factors. Related phenomena are that the first order contributions are the most important, while higher order contributions decay fast. Finally one observes that the largest interactions (second order contributions) are combination of the strongest factors. See for instance [67].
6.2. Surrogate models. In industrial applications, when the objective functions at hand could be non-differentiable, or may be computationally too expensive, preventing the computation of derivatives, we figure that the applicability of the algorithm proposed here will be significantly extended by using surrogate models. There exists an extensive literature developed in recent years on this subject (see [21, 22, 45, 46] and the references therein), also with specific applications to multiobjective optimization [24, 25].

The procedures of this paper can be adapted applying the Algorithms 1 and 2 to a surrogate model \( \tilde{u} \) fitted to the values of the true functions \( u \) computed on the given data points. On the outcoming candidate points, new evaluations of \( u \) are to be computed, and a new surrogate model fitted to the increased dataset. This reduces the computational effort for computing derivatives and furthermore prevents premature
stopping of the optimization process due to accidental failure of function evaluation at some data point. Again, the convergence to the Pareto sets of the true functions is guaranteed via global analysis.
