We use daily data on bilateral interbank exposures and monthly bank balance sheets to study network characteristics of the Russian interbank market over Aug 1998 - Oct 2004. Specifically, we examine the distributions of (un)directed (un)weighted degree, nodal attributes (bank assets, capital and capital-to-assets ratio) and edge weights (loan size and counterparty exposure). We search for the theoretical distribution that fits the data best and report the “best” fit parameters. We observe that all studied distributions are heavy tailed. The fat tail typically contains 20% of the data and can be systematically described by a truncated power law. In most cases, however, separating the bulk and tail parts of the data is hard, so we proceed to study the full range of the events. We find that the stretched exponential and the log-normal distributions fit the full range of the data best. These conclusions are robust to 1) whether we aggregate the data over a week, month, quarter or year; 2) whether we look at the “growth” versus “maturity” phases of interbank market development; and 3) with minor exceptions, whether we look at the “normal” versus “crisis” operation periods. In line with prior research, we find that the network topology changes greatly as the interbank market moves from a “normal” to a “crisis” operation period.

I. INTRODUCTION

The frequency of an event follows a power law when that frequency varies as a power of some attribute of that event (e.g. its size). Power-law distributions have been claimed to occur in an extraordinarily diverse range of phenomena from the sizes of wars, earthquakes and computer files to the numbers of papers scientists write and citations those papers receive [1]. In economics and finance, power laws have been documented for income and wealth [2], the size of cities and firms, stock market returns, trading volume, international trade, and executive pay [3]. Most relevant to this paper, the tail parts of interbank network characteristics, such as degree distribution, have been shown to follow a power law too (see [4] for Brazil, [5, 6] for Austria, [7] for the US Fedwire system, and [8] for the commercial banks in the US). This ubiquitous presence of power laws has resulted in an extensive search for universal dynamics that can explain their existence (see [9, 10] for examples of such search in interbank networks).

Recently, however, Clauset et. al. [11] (followed by [12]) call these findings into question. In particular, they criticize the commonly used methods for analyzing power-law data, such as least-squares fitting, which can produce inaccurate estimates of parameters for power-law distributions or provide no indication of whether the data obey a power law at all. Clauset et. al. propose a statistical framework for discerning and quantifying power-law behavior in empirical data and apply that framework to twenty-four real-world data sets, each of which has been conjectured to follow a power law. For most datasets they find moderate to weak evidence in favor of power laws.

This debate about the potential of power laws to capture the underlying network dynamics is important for economic policy. For example, current research on con-
tagion in interbank markets often relies on a scale-free topology to simulate the interbank network [13, 14]. This choice likely affects the outcome of conducted stress tests (as is explicitly confirmed by [14]) and, therefore, the policy implications stemming from them. Yet the evidence supporting this choice is not ironclad.

This paper contributes to the debate by providing a detailed analysis of the network characteristics of a real interbank network over an extended period of time. We use daily data on bilateral interbank exposures and monthly bank balance sheets to study network characteristics of the Russian interbank market over Aug 1998 - Oct 2004. We focus on measures that represent essential input for most of the interbank contagion simulations. Specifically, we examine the distributions of (un)directed (un)weighted degree, nodal attributes (bank assets, capital and capital-to-assets ratio) and edge weights (loan size and counterparty exposure). Using the methodology of [11] we set up a horse race between the different theoretical distributions to find one that fits the data best. We then study the time evolution of the best-fit parameters.

We observe that all studied distributions are heavy tailed. The fat tail typically contains 20% of the data and can be systematically described by a truncated power law. In most cases, however, separating the bulk and tail parts of the data is hard, so we proceed to study the full range of the events. We find that the stretched exponential and the log-normal distributions fit the full range of the data best. Our conclusions turn out to be robust to whether we aggregate the data over a week, month, quarter or year. Further, we find no qualitative difference between the “growth” and “maturity” phases of interbank market development and little difference between the “crisis” and “non-crisis” periods.

Sec. II describes our data, defines the network measures we study, and summarizes the conclusions from previous studies of those measures. Sec. III and IV, respectively, describe and illustrate the methodology we use to find the theoretical distribution that fits the data best. Sec. V reports the results. Sec. VI concludes.

II. DATA AND DEFINITIONS

A. Data Source

Mobile, a private financial information agency, provided us with two datasets for the period Aug 1998 - Oct 2004. [29] The information in the datasets is a part of standard disclosure requirements and is supplied to the regulator on a monthly basis. The first dataset, described in [15], contains monthly bank balances for most Russian banks. From this dataset we take two variables: total assets and capital. The second dataset contains monthly reports “On Interbank Loans and Deposits” (official form’s code 0409501) and represents a register of all interbank loans issued in the Russian market. For each loan we know its size, interest rate, issuer, receiver, reporting date and maturity date.

On average, about half of the Russian banks are active on the interbank market. Consequently, the analysis of interbank network measures includes fewer banks than the analysis of balance sheet indicators.

B. Network Measures

We use the two aforementioned datasets to construct an interbank network with banks as nodes and mutual contracts representing edges. This procedure is performed for aggregated data covering various time intervals. In every situation, we construct three versions of the interbank network, which differ in the level of detail in quantifying the edges. In the undirected version, an undirected unweighted edge is established between banks if they exchange money on the interbank market during the considered time period. For the directed versions, we discriminate between the issuer and the receiver of the interbank loan. A directed edge, which points from issuer to receiver, is established if the issuer has lent money to the receiver in the considered period. In the multidirected version, every interbank loan is represented by a directed edge pointing from issuer to receiver. This implies there can be several edges between pairs of nodes.

In this paper we focus on network characteristics that represent essential input for typical interbank contagion simulations [13, 16–18]. We distinguish three types of network characteristics: nodal attributes, edge weights and various measures of a node’s centrality.

We consider three nodal attributes: bank capital, total assets and leverage. Total assets proxy for bank size. Capital measures its financial buffer. Leverage is defined as capital divided by total assets. We exclude banks with negative assets (data errors) or negative capital (banks in effective default) from our sample.

Edge weights are measured separately for the directed and the multidirected network. For the former, the edge weight equals counterparty exposure, that is, the total amount of money the issuer has lent to the receiver in the considered time period.

For the multidirected network, the edge weight equals the size of the issued loan.

We consider various measures of a node’s centrality. For an undirected network, we define the degree of a node as the number of edges connected to that node. It measures the number of counterparties a bank has on the interbank market. For the directed network, an indegree (out-degree) of a node is the number of incoming (outgoing) edges; it measures the number of interbank lenders (borrowers) a bank has. For the multidirected network, an in-degree (out-degree) is the number of received (issued) loans. Finally, for each bank we define the total in-exposure (out-exposure) as the total amount of money borrowed from (lent to) the market.

The interbank network characteristics we consider in
this paper have already been studied for a number of countries. Here we summarize the main findings of those studies.

The majority of studies find numerous heavy tailed variables in the interbank network. In addition, many authors propose a power law as the best-fit candidate to (at least the tail of) the empirical distribution. In particular, Goddard et al. [8] find that the asset size distribution of U.S. commercial banks is well described by a truncated lognormal, while the tail part is well fitted with a power law. Cont et al. [4] obtain fair fits to the tails of the in-degree, out-degree, total degree, and exposure size distributions of the Brazilian interbank network with power laws. Soramaki et al. [7] put forward a power law to describe the out-degree distribution, as well as the number of transactions between pairs of banks in the US Fedwire system. In the Austrian interbank market the loan size distribution is well described by a power law [5, 6]. That same study also examines the degree distribution of the undirected network and the in- and out-degree distribution of the directed alternative. Each of these three distributions is seemingly well described by two power laws, one for the low-degree region and one for the tail part. Finally, Iori et al. [19] investigate the distributions of the in-degree, out-degree and exposure of the individual banks in the Italian market. The authors do not attempt to fit their data with some theoretical distribution. They do find, however, a structural difference in the network topology between the months of the global financial crisis of 2008 and normal operating months.

Few studies, however, consider alternate theoretical distributions as candidates to describe their data. The ones that do [20], in fact, cast doubt on the ability of power laws to provide the best empirical fit. In what follows, we too consider an extensive list of alternative theoretical distributions and identify those that describe both the tail and the entire distribution better than the power law. Along the way, we apply a criterion which allows us to discriminate between the tail and the bulk parts of the data.

C. Descriptive Statistics

Different phases of the interbank market development (for example, growth versus maturity, or crisis versus non-crisis) may be guided by a different data generating mechanism. For example, Iori et al. [19] find a structural difference in the Italian interbank network topology before versus during the 2008 financial crisis. This finding suggests that the choice of the distribution that best fits the data may vary over time, and in particular may differ between crisis and non-crisis periods. In Sect. V we check whether such variation exists. In this section, we provide evidence that the Russian interbank market, indeed, went through some distinct development phases.

Fig. 1 shows the time series of the number of banks active on the interbank market and of the number of issued loans. For this figure we use data aggregated over a month. Over 1998-2002 the interbank network experiences growth: we observe a steady and comparable increase in the number of active banks and of issued loans. After 2002, the interbank network gradually matures: the number of active banks flattens out while the number of loans per bank grows. Note, however, the strong variation in the number of issued loans from the second half of 2003 onwards.

As is clearly indicated in Fig. 1, our sample period includes two crises: one in August 1998 and one in the summer of 2004. Both crises resulted in a partial meltdown of the Russian interbank market. They coincide with the edges of the sample period and are clearly marked by a reduction in the number of active banks and issued loans. The first crisis got triggered on August 17, 1998 when Russia abandoned its exchange rate regime, defaulted on its domestic public debt and declared a moratorium on all private foreign liabilities. The second crisis was ignited by an investigation of banks accused of money laundering and sponsorship of terrorism. This gave rise to a wave of distrust among banks and a consequent liquidity drought.

Fig. 2 illustrates the impact of Aug 1998 crisis on the Russian interbank network. Nodes are banks, and directed edges represent issued loans. The first panel shows the activity in the market in the two weeks leading up to the seizure, whereas the second panel covers the two weeks after the collapse. Evidently, we see a decrease in the number of active banks, from 87 to 65, and in the number of loans granted, from 507 to 96. When considering the structure in this unweighted multidirected network we can find a clear distinction between the “normal” and “crisis” periods. The technique of Ref. [21] can be
FIG. 2: (Color online) The activity on the interbank market in the two weeks leading up to August 17, 1998 (top panel) and the two consecutive weeks (bottom panel). A bank is represented as node and each link represents an issued loan. Nodes are colored per block as defined in Ref. [21].

used to uncover groups of nodes, called blocks, which fulfill similar roles in the network. In the two weeks leading up to the crisis we get an interbank market with 5 blocks (and two isolated banks). After the crisis the number of identified blocks goes down to 3. Notably, the identified blocks interact with each other before the crisis but not after. So the crisis disintegrates the network and reconfigures banks’ role in it.

We can also see evidence of different development phases by studying the time evolution of two basic network measures: the average local clustering coefficient and the average shortest path length. For an undirected network, the local clustering coefficient $0 \leq c_u \leq 1$ of a node $u$ is the number of the edges between the nodes of the neighborhood of $u$ divided by the maximum amount that could possibly exist between them. It can be conveniently defined as in [22]

$$c_u = \frac{2T(u)}{\text{deg}(u)(\text{deg}(u) - 1)},$$

where $T(u)$ is the number of triangles (a subgraph with three nodes and three edges) attached to $u$ and $\text{deg}(u)$ is the degree of $u$. The average of this local clustering coefficient is

$$C = \frac{1}{n} \sum_{u \in G} c_u,$$  \hspace{1cm} (2)

where $n$ is the number of nodes in the network $G$ [23].

The average shortest path length $D$ is defined as

$$D = \frac{\sum_{u,v \in V} d(u,v)}{n(n-1)}$$

(3)

where $V$ is the set of nodes in the network $G$, and $d(u,v)$ is the length of the shortest path from node $u$ to $v$ [24]. In a disconnected graph $D$ can only be computed for the largest connected component.

Fig. 3 shows the time evolution of $C$ and $D$ computed per month for the largest connected component of the undirected interbank network. First, note that the local clustering coefficient averaged over all nodes and time periods ($C = 0.198$) is nearly identical to the one reported by [4] for the Brazilian interbank market ($C = 0.2$). In contrast, the average shortest path length ($D \approx 3$) is notably higher compared to Austrian ($D = 2$) [5] and Mexican ($D = 1.7$) [25] interbank networks.

$C$ and $D$ tend to move in the opposite direction: three months after the first crisis hits $C$ drops while $D$ spikes; during the growing phase of the network (1999-2002) $C$ grows while $D$ falls; during the mature phase (2002-2004) both measures stabilize at $C \approx 0.22$ and $D \approx 3$; finally, during the 2004 crisis $C$ drops while $D$ spikes again. The average local clustering coefficient $C$, however, tends to have bigger fluctuations from period to period. In contrast, the time series of the average shortest path length is very smooth, and the only two obvious spikes occur around the two crises. Clearly, those crises disrupted the overall network structure: the liquidity drought, which is equivalent to the pruning of links, caused a significant increase in the average shortest path length. Even the decrease in the number of nodes, and hence shrinking of the network, could not offset this effect. The 1998 spike in $D$ is particularly remarkable given we only consider the largest connected component, that is, about one third of the nodes (see Fig. 2). We thus conclude that the average shortest path length has some potential to discriminate between the “normal” and the “crisis” operation periods of the interbank market.

III. METHODOLOGY

For each network measure we test whether the power law or an alternate fat-tailed distribution fits the data best. First, we fit distributions to the tail, then to the entire data range. Along the way, we apply a criterion which allows us to discriminate between the tail and the bulk parts of the data.

To study the tail we adopt the methodology of Ref. [11]. First, we fit a power law (PL) to the data to
determine the starting point of the tail part (the so-called cut-off $x_{\text{min}}$ of the scaling range). Then we fit each of the theoretical distributions to the tail using maximum likelihood (ML). Finally, we use a relative goodness-of-fit test to select the distribution that fits the data best. We consider the same selection of theoretical distributions as in Ref. [11]. Their functional forms are listed in Table I and involve one or two free parameters.

For completeness and to introduce the notation we briefly sketch the methodology of Ref. [11]. Consider a given ordered data set $\{x_j, j = 1, \ldots, N\}$. Every entry $x_j$ is a potential $x_{\text{min}}$ and for each of those we compute the ML estimate of the power-law exponent $\alpha$

\[
\hat{\alpha} (x_j = x_{\text{min}}) = 1 + (N - j + 1) \left[ \sum_{i=j}^{N} \ln \frac{x_i}{x_{\text{min}}} \right].
\]  

We then use the Kolmogorov-Smirnov test to select the optimum $x_{\text{min}}$. It is defined as the cut-off which minimizes the quantity

\[
Z = \max_{x \geq x_{\text{min}}} | S(x) - P(x) |.
\]

Here, $S(x)$ is the cumulative distribution function (CDF) of the observed values for $x_j \geq x_{\text{min}}$, and $P(x) = \frac{C}{x^{-\alpha+1}} (x^{-\alpha+1} - x_{\text{min}}^{-\alpha+1})$ is the CDF of the power-law fit to the tail part of the data.

In the next step, for given $x_{\text{min}}$, we perform ML fits to the data with the other four candidate distributions of Table I. As argued by Ref. [11], it is more useful to know which distribution is the best possible fit candidate, rather than the goodness of fit for each distribution individually. To compare the relative goodness of the different fits, we compute the likelihood ratios $R$ for the pairs of probability density functions (PDFs) $p_1(x_i)$ and $p_2(x_i)$

\[
R(p_1, p_2) = \frac{L_1}{L_2} = \prod_{i=1}^{N} \frac{p_1(x_i)}{p_2(x_i)}.
\]

The corresponding normalized loglikelihood ratios $\mathcal{R}(p_1, p_2)$ read

\[
\mathcal{R}(p_1, p_2) = \frac{1}{\sigma_{12} \sqrt{N - j + 1}} \sum_{i=j}^{N} \left[ \ln \frac{p_1(x_i)}{p_2(x_i)} \right]
\]

\[
= \frac{1}{\sigma_{12} \sqrt{N - j + 1}} \sum_{i=j}^{N} \left[ l_1^{(i)} - l_2^{(i)} \right],
\]

where $l_1^{(i)} = \ln p_k(x_i)$ and $\sigma_{12}$ is defined as

\[
\sigma_{12}^2 = \frac{1}{N - j + 1} \sum_{i=j}^{N} \left[ l_1^{(i)} - \bar{l}_1 \right] \left( \bar{l}_1 - l_1^{(i)} \right).
\]

The $\mathcal{R}(p_1, p_2)$ is positive (negative) if the data is more likely in the $p_1$ ($p_2$) distribution.

In order to guarantee that the value of $\mathcal{R}$ is not merely a product of fluctuations and that the true expectation value of $\mathcal{R}$ is zero, we compute the probability that the measured normalized log likelihood ratio has a magnitude as large or larger than the observed value $|\mathcal{R}|$. This so-called $p$-value is defined as

\[
p(\mathcal{R}) = \frac{1}{\sqrt{2\pi}} \int_{-|\mathcal{R}|}^{\infty} e^{-\frac{t^2}{2}} dt + \int_{|\mathcal{R}|}^{\infty} e^{-\frac{t^2}{2}} dt.
\]

The distribution $p_k$ with the highest value of

\[
g(p_k) = \sum_{i \neq k} \mathcal{R}(p_k, p_i)
\]

is considered as the most suitable distribution among the different candidates $\{p_i\}$. Bootstrapping and the Kolmogorov-Smirnov test are alternate methods to compute the $p$ values. Both methods, however, are subject to some pitfalls as outlined in Ref. [26].
A drawback of the above mentioned procedure is that the cut-off $x_{\text{min}}$ is determined by a power-law fit. This introduces a bias toward a PL as the best fit candidate distribution.

We stress that the above-sketched methodology of Ref. [11] can not only be applied to the analysis of the tail part of the data but also to the full range of the data by setting $x_{\text{min}} = x_1$. When considering the full range of data it is natural to select a set of theoretical distributions that encompass a Gaussian-like regime (thermal or bulk part) supplemented with a fat tail (superthermal part). Examples of such distributions include the stretched exponential and the log-normal.

IV. ILLUSTRATION OF METHODOLOGY FOR OUT-EXPOSURE DISTRIBUTION

As a prototypical example of the methodology sketched in Sec. III, we explore the out-exposure distribution for the monthly aggregated data. The data for the out-exposure distribution of January 2002 shown in Fig. 4 are exemplary for all considered 70 months (January 1999 - October 2004). The considered values for the out exposure extend over more than five orders of magnitude and the distribution can be labelled as heavy-tailed [30].

Using the methodology outlined in Sec. III we identify the tail part of the data. From Fig. 4(b) it is clear that fits to the tail part of the considered data with the two-parameter log-normal (LN), stretched exponential (SExp) and truncated power law (TPL) distributions outperform those with the one-parameter exponential (Exp) and power law (PL) distributions. The parameter $\lambda$ in the TPL accounts for the finite-size effects near the upper edge of the out-exposure distribution. For each of the 70 months in our sample we compute the ratios $R(p_1, p_2)$ of Eq. (7) for all pair combinations out of the list of five distributions of Table I. In Fig. 5 we display the time series of the $R(TPL, p_2)$ for $p_2 = \text{PL}$, Exp, SExp, and LN. We observe that $R(TPL, p_2)$ is mostly positive, which indicates that the TPL offers the best overall description of the tail of the out-exposure data. In order to test the significance of this observation, we evaluate the $p$ values. If the normalized ratio for a pair of distributions in a given month is significant at a one percent level, the data points in Fig. 5 are dotted. The figure indicates that the two-parameter TPL is a significantly better fit to the tail of the monthly-aggregated out-exposure distribution than a power law and an exponential. The TPL, however, does not provide a significantly better fit than the LN or SExp for most of the months.

Fig. 6(b) shows the time evolution of the TPL parameters. Whereas $\alpha$ fluctuates around the same average value, $\lambda$ falls over time. Hence, as time proceeds, the exponential cutoff to the power law shifts to larger values of the out-exposure.

To weigh the relative performance of the different distributions we compute their monthly $g(p_i)$ scores (see Eq. (10)). We dub $p_i$ as the “best” overall fit candidate when its $g(p_i)$ score is highest for the largest fraction of the 70 months in our sample. As can be seen in Table II, the truncated power law is the best-fit candidate in 94% of the considered months. Nevertheless, $R(TPL, SExp)$ is not significantly different from zero in 94% of the considered months as is the case with $R(TPL, PL)$ in 59% and with $R(TPL, LN)$ in 83% of the months. So we list the SExp as well as PL and LN as alternate best-fit candidates. In general, if a distribution is not significantly worse than the best-fit candidate in more than half of the months, it is mentioned in the last column of Table II. We conclude that although the tail is described best by a TPL, the fit is not significantly better than the power-law, stretched-exponential and log-normal fits.
FIG. 5: (Color online) (a) The time series of the normalized loglikelihood ratios $R(p_1 = \text{LN}, p_2)$ of Eq. (7) for the different fits to the total distribution of the monthly-aggregated out-exposure. (b) The time series of $R(p_1 = \text{TPL}, p_2)$ for the fit to the tail of the monthly-aggregated out-exposure distribution.

FIG. 6: (Color online) The time evolution of the parameters for the best fit to the total (a) and tail (b) part of the out-exposure distributions. The total data range is fitted with a log-normal distribution with parameters $\mu$ (solid line) and $\sigma$ (dashed line). The tail part is fitted with a truncated power-law distribution with parameters $\alpha$ (solid line) and $\lambda$ (dashed line).
stage of the network whereas $\sigma$ intervals to aggregate the data. Beside the networks we study the out-exposure and consider different time widths affects the conclusions with regard to the "best" few nodes or links are added (see Fig. 1).

Now, we investigate in how far the size of the time bin increases during the "growth" decreases, and both tend to flatten out in the "mature" phase of the network when $\mu$ parameters. The parameter shows the time evolution of the log-normal fit parameters of the aggregates. If we calculate $g(p_k)$ for every distribution in Table I, we find that the log-normal is the preferred candidate to fit each dataset, although, again, the stretched exponential is not significantly worse. For the tail part, the truncated power law stays on top too. Because the data has a monthly periodicity, linked to the monthly compliance with regulatory requirements, aggregating the data monthly is the most natural thing to do.

To check whether these observations can be generalized, we repeat the illustrated procedure for weekly, quarterly, and yearly aggregates. Tab. IV shows the "best" fit candidate for the tail and entire distribution over our data sample. For the tail part, the TPL is preferred over the others for each aggregate. It does so in 85% of the weeks and up to 100% of the years. For the entire distribution, the LN is always preferred.

\section*{V. RESULTS}

We now turn our attention to the distributions covering all out-exposure data points, from small to large. Again we consider the five PDFs of Table I. From the ML fits, for example for January 2002 displayed in Fig. 4(a), we immediately notice that the exponential and power law do not fit the entire range of data well. This is a clear indication of the fact that the distribution of the out-exposure has both a thermal (Gaussian-like) and a superthermal (fat tail) part. Fig. 5 shows the normalized loglikelihood ratios $R(p_1 = LN, p_2)$ over time. Using the same criteria as for the tail part, we conclude that the log-normal is the best fit candidate for 80% of the 70 months studied.

We also find that the stretched exponential is not significantly worse in 57% of the cases, which is reflected in the persistently small values of their likelihood ratios in the top panel of Fig. 5. During the 2004 crisis the stretched exponential has a significantly better fit than the log-normal. As the number of interbank loans is stretched exponential has a significantly better fit than the log-normal. As the number of interbank loans is sub- stretched exponential has a significantly better fit than the log-normal. As the number of interbank loans is sub- stretched exponential has a significantly better fit than the log-normal. As the number of interbank loans is sub-

\end{table}
FIG. 7: (Color online) The CCDF of the out-exposure distribution from a network aggregated with data from one week (week 2 of January 2002), from one month (January 2002), from one quarter (first quarter of 2002), and one year (2002). We also show the respective stretched exponential and log-normal fits.

the $x_{\min}$, which marks the lower boundary of the tail parts of the distributions and results from minimizing the quantity $Z$ of Eq. (5), is close to the upper edge of the distribution. Under those circumstances the identified tail does not hold a sufficient amount of datapoints to perform a meaningful fit. This is particularly common during the 1998 interbank network collapse. For this reason, we only study the best-fit parameters from January 1999 onwards.

A prototypical example of a data set for which the fit with the functions of Table I is not fully satisfactory is shown in Fig. 8. The figure includes the loan size and counterparty-exposure measures for January 2004. Whereas the TPL is a good match for the tail parts of the data, the “best” fit to the entire range of the data with a LN distribution clearly underestimates the probability of events in the tail. Fig. 9 displays for January 2004 the “tail” and “bulk+tail” parts of the 10 other interbank network measures considered. It is clear that the data can be reasonably well described by the adopted procedure and proposed theoretical distributions.

Table II reports our findings on the tail parts of the empirical distributions. The second column shows the percentage of data points assigned to the tail via the Kolmogorov-Smirnov criterion of Eq. (5). This number averages to about 20% across the considered network measures but varies a lot. In particular, the loan size, counterparty exposure, and directed out-degree have relatively few events in the tail. For most of the 70 months included in the analysis, the truncated power law outperforms, according to our methodology, the other four candidates for every measure. In Table II the time-averaged values for the $\alpha$ and $\lambda$ parameters are also reported. The power $\alpha$ is consistently of the order of two. It emerges from our studies that a fat tail is a characteristic feature of the measurable quantities of an interbank system. We notice that $\lambda$ is very volatile.

Upon evaluating the last column of Table II, we find that although the truncated power law systematically provides the best fit, the other candidates are hardly significantly worse at the 1 percent level. This observation is particularly true for the unweighted degree measures which are discrete. In fact, for the degree measures, none of the five distribution candidates can be conclusively labeled as representing the best fit to the data. We note that the fraction of events located in the tail fluctuates a lot. This hints that a more integrated approach whereby the bulk and the tail parts of the data are simultaneously fitted with a non-Gaussian distribution may lead to a more stable description of the network features.
FIG. 9: (Color online) The CCDF for 10 interbank network measures for the monthly aggregated data in January 2004. Panels (a-f) display the tails parts of the data together with the PL (grey) and TPL (green) fits. Panels (g-l) contain the data over the entire range together with the "best" fit from Table III. For illustrative reasons, in those panels with two measures, the data of the second measure have been shifted vertically by multiplying them by a scaling factor of 0.5.
Table III summarizes our fits to the entire distributions of all 12 network measures over all 70 months using monthly-aggregated data. The asset, capital, leverage, loan sizes, as well as the counterparty-exposure and in-exposure distributions are described significantly best by a log-normal. The various degree distributions prefer the stretched exponential, which is on average not significantly better than the log-normal and/or the truncated power law. For those network measures for which the stretched exponential represents the best fit, we observe that the parameter $\lambda$ is very volatile. It is worth noting that the stretched exponential has been put forward as a natural fat tail distribution for many physical and economic phenomena which cannot be satisfactorily described by a power law [27]. In general, the parameters entering the fits to the tail parts are subject to larger fluctuations than those entering the distributions for the complete data set.

Our results compare well with some of the existing studies of interbank networks, but differ from others. Specifically, our findings are in line with Goddard et al. [8] who study U.S. banks: the log-normal distribution fits the bulk part of the asset-size data well, while the power law does the same for the tail part. Our findings are not too different from those of Cont et al. [4] for the Brazilian interbank network: while our TPL fits to the tails of various degree distributions (see Table II) deliver values of $\alpha$ between 1.7 and 2.2, Cont et al. [4] report power-law exponents between 2.2 and 2.8 ($\alpha = 2.54$ for total degree, $\alpha = 2.46$ for in-degree, $\alpha = 2.83$ for out-degree, and $\alpha = 2.27$ for out-exposure size). Finally, in contrast to [5] studying the Austrian interbank market we do not find that the power law provides a good fit to the entire loan-size distribution ([5] report $\alpha = 1.87$). Their power-law exponents reported for the tails of total and in-degree distributions (resp. $\alpha = 2.0$ and $\alpha = 3.11$) are comparable to the TPL values in Table II, while their out-degree $\alpha = 1.72$ differs substantially.

The most extensive study of interbank distributions was performed for the e-mid market [20]. In line with this work, the authors consider both the complete and tail parts of the distributions and report results for daily and quarterly time aggregates. For the quarterly aggregates of the in-, out- and total degree distribution, a stretched exponential emerged as the best fit to the entire distribution. This confirms our findings. A log normal was reported as a best fit to the tail parts of the data. We also find that the LN can reasonably account for the tail parts. It is slightly outperformed by the truncated power law (which was not included in the set of possible distributions in the work of Ref. [20]) and flags as not significantly worse in our table. For the quarterly aggregated number of transactions, a network feature comparable to the multidirected degree considered here, they also find similar results as for the regular degrees.

Upon scrutiny of the time evolution of the fitted distributions and their parameters, we do not find any systematic changes in the distributions which emerge as best fit to the data, between the “growth” phase (1999-2002) and the “mature” phase (2002-2004). In line with the expectations, however, the extracted parameters are subject to smaller variations as the network grows and the number of nodes and edges increases.

As already mentioned, our data set covers two crises, the first in August 1998 and the second in the summer of 2004. We would like to know if the best-fit candidates for the crisis periods are different than the ones for the normal operation periods.

As a consequence of the moratorium in August 1998, the interbank market collapsed in September, and then again in December 1998 (see Fig. 1). Due to this collapse, the network is too small and their are too few transactions to gather proper statistics. Fits to the data in this period are inconclusive for most of the measures, and hence are not included in the overall discussion.

During the second crisis period, the network does stay large enough to have proper statistics. From Fig. 5 it is clear that the stretched exponential distribution is significantly better than the log-normal from mid 2004 onwards. Thus, for the out-exposure (as well as the in-exposure), there is a difference between pre- and post-crisis best-fit candidates. For the other measures, however, we find that the same distributions are preferred in “crisis” as in ”normal” operation periods.

To end this section, we test the qualitative robustness of the obtained results using different time windows. This is particular important in view of the fact that a recent study has shown that the interbank network properties depend on the aggregation period [28]. To check if the same distribution is preferred for different aggregates, we repeat the monthly procedure for weekly, quarterly, and yearly aggregates. Tab. IV shows the “best” fit for each measure-aggregate pair and the percentage of the bins it is considered so. For the tail parts, we find that the TPL can be considered as the best overall fit candidate. We notice that in general the TPL becomes more preferred as the bin width increases. For each measure, the favoured fits to the entire distribution stay the same for different bin widths.

VI. CONCLUSION

In this paper we use daily data on bilateral interbank exposures and monthly bank balance sheets to study network characteristics of the Russian interbank market over Aug 1998 - Oct 2004. Specifically, we examine the distributions of (un)directed (un)weighted degree, nodal attributes (bank assets, capital and capital-to-assets ratio) and edge weights (loan size and counterparty exposure). Using the methodology of [11] we set up a horse race between the different theoretical distributions to find one that fits the data best.

In line with the existing literature, we observe that all studied distributions are heavy tailed with the tail typically containing 20% of the data. The tail is best
TABLE III: Summary of the results of the fits to the monthly-aggregated data of all the network features considered in this work. We list the distribution which provides the best fit to the full range of the data ("bulk"+"tail"), together with the percentage of months for which it comes out “best” according to the criterion of Eq. (10). Columns 3 and 4 provide the average values of the parameters of the best-fit distribution. The last column list the distributions which are not significantly (at the 1 percent level) worse for more than half of the 70 months (January 1999 - October 2004) considered, together with the percentage of months for which this is the situation.

| Measure                      | Best fit (%) | Parameter 1   | Parameter 2   | Alternative fit (%) |
|------------------------------|--------------|---------------|---------------|---------------------|
| Asset Size                   | LN (100)     | $\mu = 5.45 \pm 0.63$ $\sigma = 1.91 \pm 0.02$ | None          |
| Capital Size                 | LN (100)     | $\mu = 4.64 \pm 0.53$ $\sigma = 1.51 \pm 0.03$ | None          |
| Leverage                     | LN (99)      | $\mu = 1.57 \pm 0.05$ $\sigma = 0.74 \pm 0.01$ | None          |
| Loan Size                    | LN (100)     | $\mu = 2.54 \pm 0.34$ $\sigma = 1.27 \pm 0.08$ | None          |
| Counterparty-exposure        | LN (99)      | $\mu = 3.33 \pm 0.31$ $\sigma = 1.56 \pm 0.13$ | None          |
| Undirected Degree            | SExp (54)    | $\lambda = 0.29 \pm 0.20$ $\beta = 0.55 \pm 0.06$ | LN (94)       |
| Directed In-Degree           | SExp (66)    | $\lambda = 0.41 \pm 0.27$ $\beta = 0.46 \pm 0.07$ | TPL (91), LN (71) |
| Directed Out-Degree          | SExp (83)    | $\lambda = 0.43 \pm 0.39$ $\beta = 0.60 \pm 0.05$ | TPL (51), LN (97) |
| Multidirected In-Degree      | SExp (80)    | $\lambda = 0.29 \pm 0.35$ $\beta = 0.43 \pm 0.07$ | TPL (90)      |
| Multidirected Out-Degree     | SExp (73)    | $\lambda = 0.19 \pm 0.26$ $\beta = 0.53 \pm 0.09$ | LN (80)       |
| In-Exposure                  | LN (83)      | $\mu = 4.26 \pm 0.83$ $\sigma = 2.37 \pm 0.09$ | None          |
| Out-Exposure                 | LN (80)      | $\mu = 4.55 \pm 0.65$ $\sigma = 2.13 \pm 0.10$ | SExp (57)     |

TABLE IV: Robustness of the “best” fits for different aggregates. This table shows for each measure-aggregate pair the preferred fit candidate as well as the percentage of the bins it was considered so. This is done for fit of tail as well as total.

| Measure                | Tail                  | Bulk + Tail                |
|------------------------|-----------------------|---------------------------|
|                        | Week | Month | Quarter | Year | Week | Month | Quarter | Year |
| Loan Size              | TPL (70) | TPL (75) | TPL (78) | TPL (80) | LN (95) | LN (100) | LN (100) | LN (100) |
| Counterparty-exposure  | TPL (82) | TPL (80) | TPL (83) | TPL (80) | LN (94) | LN (99) | LN (100) | LN (100) |
| Undirected Degree      | TPL (93) | TPL (94) | TPL (90) | TPL (100) | SExp (66) | SExp (54) | SExp (52) | SExp (80) |
| Directed In-Degree     | TPL (92) | TPL (97) | TPL (95) | TPL (100) | SExp (58) | SExp (66) | SExp (65) | SExp (60) |
| Directed Out-Degree    | TPL (92) | TPL (97) | TPL (95) | TPL (100) | SExp (64) | SExp (83) | SExp (87) | SExp (100) |
| Multidirected In-Degree| TPL (92) | TPL (97) | TPL (95) | TPL (100) | SExp (78) | SExp (80) | SExp (87) | SExp (100) |
| Multidirected Out-Degree| TPL (79) | TPL (93) | TPL (90) | TPL (100) | SExp (67) | SExp (73) | SExp (87) | SExp (100) |
| In-Exposure            | TPL (94) | TPL (97) | TPL (95) | TPL (100) | LN (74) | LN (83) | LN (74) | LN (60) |
| Out-Exposure           | TPL (85) | TPL (94) | TPL (100) | TPL (100) | LN (83) | LN (80) | LN (57) | LN (80) |

described by a truncated power law, although the fit of other candidate distributions is only marginally worse.

In most cases, separating the bulk and tail parts of the data turns out to be hard, and the proportion of observations assigned to the tail varies a lot. More stable fits to the data are obtained in an integrated approach that accounts for both the Gaussian and the non-Gaussian parts of the distributions. We find two distributions that fit the full range of the data best: the stretched exponential for measures related to unweighted degree and the log-normal for everything else. In case of the former, the log-normal performs only marginally worse.

Our conclusions turn out to be robust to whether we aggregate the data over a week, month, quarter or year. Further, we find no qualitative difference between the “growth” and “maturity” phases of interbank market development and little difference between the “crisis” and “non-crisis” periods.

Our findings support the recent call [11, 12] for more rigorous statistical tests to detect power-law behavior in empirical data. While for most variables we find that the power law fits the tail of the distribution reasonably well, it is:

1. almost never the best candidate to describe the tail;
2. *typically not a good* candidate to describe the whole distribution.

Our findings echo those of Ref. [20] who also find that the power law provides an inferior fit, compared to alternative distributions, to their overnight money market data coming from the e-MID trading platform. We thus tend to conclude that the evidence on power laws is not (yet) strong enough to warrant their widespread use in policy simulations. From the study presented in this work we provide alternate distributions and corresponding parameters which can systematically and robustly capture the interbank network measures. We deem that those distributions represent a more realistic account of the interbank network structure than the widely used power laws and could facilitate more realistic contagion modeling.
