Abstract
Splenic injury is a rare but potentially life-threatening complication of endoscopy, with very few cases of endoscopic retrograde cholangiopancreatography (ERCP)-induced injury reported in the literature. Here we report a patient with chronic alcoholic pancreatitis who was diagnosed with a sub-capsular splenic laceration nearly 6 days after an ERCP. Clinicians should be alerted to the potential post-procedure complications associated with ERCP, particularly as this procedure is being utilized more frequently for the management of patients with complex hepatobiliary and pancreatic conditions.

Introduction

With the increased use of endoscopic retrograde cholangiopancreatography (ERCP) for patients with pancreatico-biliary disease, a subset of specific procedural risk factors has been established, including pancreatitis, perforation, hemorrhage, and infection [1]. The procedure itself carries a complication rate between 5 and 10% [2], but some of the rarer complications are not usually considered in the immediate post-procedure time frame. An uncommon but potentially life-threatening complication is splenic laceration, for which there are few reported cases and even less predictors of occurrence. Here we present a patient with chronic alcoholic pancreatitis who was diagnosed with a splenic laceration after undergoing ERCP and suggest that chronic pancreatitis should be considered a risk factor for this potentially fatal complication.
Case Report

A 48-year-old male with a history of chronic pancreatitis and multiple previous ERCPs for stenting of a persistent common bile duct stricture underwent an additional ERCP for a stent exchange. His last ERCP was approximately 3 months prior at which time a biliary duct stent was removed and a pancreatic duct stent was successfully replaced. Unfortunately, the patient’s symptoms of chronic abdominal pain persisted despite these interventions, and he was referred for an additional ERCP. During this procedure, ampullary cannulation was performed without difficulty, and cholangiography revealed a chronic, tight distal common bile duct stricture with dilation of the common hepatic duct. No stones were detected after multiple balloon sweeps, and a replacement biliary duct stent was deployed because of inadequate drainage. A prominent stricture in the head region of the pancreas was detected and unchanged compared to the previous ERCP, and the previously placed pancreatic duct stent was removed without incident. The total procedure time was approximately 45 minutes. There were no unplanned events during the ERCP and the patient was sent home post-procedure without any noted complaint.

Six days later, he presented to an outside facility with progressive, localized left upper quadrant abdominal pain, and was admitted after axial computed tomography (CT) of the abdomen and pelvis revealed a splenic laceration with associated subcapsular hematoma (fig. 1). The patient denied recent trauma and was subsequently transferred to our facility, where admission laboratory data revealed a hemoglobin of 9.7 g/dl, a nearly 2-gram decline post-ERCP. Liver function tests, lipase and amylase levels, and coagulation markers were normal. Vital signs did not reveal tachycardia or hypotension. Physical exam demonstrated vague tenderness along the left upper quadrant with radiation to the left shoulder. He was managed conservatively after surgical consultation with serial abdominal exams, interval ultrasounds and pain control, and was discharged in good condition after 5 days. Follow-up CT imaging 1 month post-discharge revealed progressive resolution of the splenic hematoma.

Discussion

Splenic injury is a rare but known complication of endoscopy, reported most commonly after colonoscopy. Predisposing factors include a decrease in mobility between the spleen and surrounding organs, excess traction on the splenocolic and gastroepiploic ligaments, and direct trauma to the spleen [3]. Since the first described post-ERCP case in a patient with gallstone pancreatitis [4], only 11 total cases of splenic injury have been reported in the timeframe post-ERCP [4–14]. Several pathologic findings of the spleen have been categorized, including laceration [5], subcapsular hematoma [6], short gastric vessel avulsion [7], and direct tearing of the splenic capsule [8].

In our review of the literature, the only recurrent, associated variable for ERCP-induced splenic injury is chronic pancreatitis [8–11], as was the case in this patient. The mechanism of injury is possibly related to the intimate relationship between the splenic hilum and pancreatic tail, which ultimately permits direct inflammatory spread into the spleen. In fact, spontaneous splenic parenchymal complications ranging from subcapsular hematoma to complete organ rupture are being increasingly reported as sequelae of acute and chronic pancreatitis [15]. In our case, chronic calcific pancreatitis related to alcohol consumption was evident by extensive pancreatic calcifications and a significantly dilated common bile duct visualized on imaging studies (fig. 2). This patient’s chronic pancreatitis had unfortunately progressed both clinically and radiographically over a period of several months despite multiple ERCPs and stenting of biliary and pancreatic ductal strictures. It is entirely plausible that the resulting calcification and fibrosis between the
supporting ligaments of the stomach, pancreas, and spleen may then lead to excessive mechanical tension and potential for intra-procedural splenic injury when significant scope pressure is introduced, as can occur with gastric bowing of the scope during ERCP. This increases the risk of traction injury to the spleen during endoscope manipulation in the stomach, ultimately causing splenic tearing or vascular avulsion.

This case emphasizes the need for awareness of splenic injury in patients with persistent post-ERCP left upper quadrant abdominal pain, particularly when seen in conjunction with hemodynamic instability or acute anemia developing within the timeframe post-procedure. Whereas other reports showed a lag time of up to 72 h after endoscopy [12], our case is unique because of the delayed presentation and diagnosis of a large sub-capsular hematoma nearly 6 days after the index ERCP. The association with chronic pancreatitis and this complication bears special mention as it is seen in this case and 4 other reports as noted. We suggest that although the data are retrospective and associative in nature, chronic pancreatitis could be considered a risk factor for this rare but serious complication of ERCP. Recognition of this potentially life-threatening condition requires a high index of suspicion in order to achieve proper diagnosis and best management of the patient.
